Rosaceæ is divided into eight tribes, viz., *Chrysobalanææ*, *Amygdalææ*, *Spiracææ*, *Neuradææ*, *Dryadææ*, *Sanguisorbææ*, *Rosææ*, and *Pomacææ*. The *Amygdalææ* is distinguished from the other *Rosaceæ*, because it is remarkable for containing plants which, notwithstanding they all bear eatable fruits, furnish from their leaves, their blossoms, and even from their seeds, one of the most subtle and powerful vegetable poisons known. The deleterious principle, separated by modern chemistry and named prussic acid, although so poisonous in a concentrated form, rarely exists in such proportion to the sugar, mucilage, and other innocuous substances, with which it is naturally combined, as to be in any degree injurious. Hence, bitter almonds, peach and plum stones, and cherry-laurel leaves, have been favourite ingredients with cooks and confectioners to give a pleasant flavour to custards, puddings, and jellies; and several of our most excellent liqueurs, such as noyau, ratafia, and maraschino, owe their flavour to this subtle poison.

The rose, the strawberry, and their associates are herbaceous or shrubby, but never atherosecent plants, with alternate leaves, either simple or compound, and almost universally furnished with stipules. The inflorescence is variable, the flowers monoclinous, rarely by abortion separated; very prone to become double, and in colour red, white, or yellow, but never blue; the calyx of four or five sepals, and more or less connected; the fifth or odd lobe being axial or posterior; the torus is variable, sometimes forming an annular disk, at others becoming large and hemispherical, or lining the urceolate tube of the calyx; the petals are equal, with short claws, perigenous, five in number, and rarely absent; the stamens are indefinite; the filaments free; anthers innate, two-celled, and opening lengthwise; the ovaries are several, superior, and mostly free, one-celled and one-seeded; the styles are lateral, exerted just below the apex of the carpel, and the stigma simple; the fruit either one-seeded nuts or akenia, occasionally becoming drupeolæ. This description is applicable to the strawberry, bramble, raspberry, dewberry, cloud-berry, &c.

ROSCOEÆ (Smith). A genus of Nepalese herbaceous plants, belonging to *Scitamineæ*. The species thrive in loam and peat-earth, flower freely, and are increased by division.

ROSE ACACIA is the *Robinia hispida* of Linneus, one of our most ornamental shrubby plants. They are usually propagated by grafting on the common *R. pseudacacia*. By pruning back the shoots which bear the first flowers, they may be made to flower a second time in the autumn.

ROSMARINUS (Linneus). A genus of two species, bearing diandrous flowers, and belonging to

the natural order *Labiata*. The *R. officinalis* is a well known aromatic-scented plant, for which it has been long cultivated in gardens. Burnett says it gives its fragrance to Hungary-water; it is likewise one of the ingredients employed in the manufacture of *eau-de-Cologne*, and it enters into the composition of *four thieves' vinegar*, once so famed for its supposed power of preventing the spread of contagious diseases. Rosemary has some reputation as a cephalic medicine, relieving the headach, and exciting the mind to vigorous action. Hence it has been called the herb of memory and repentance. Hence also its use as a symbol of fidelity, and its introduction both into wedding-garlands and funeral-wreaths; and still in many of our distant counties it is customary with the mourners to wear sprigs of the plant, and strew them on the grave.

ROTTLERA (Roxburgh). A genus of evergreen shrubs, natives of the East Indies and Brazil. The flowers are diœcious, and the genus belongs to *Euphorbiacææ*. The *R. tinctoria* is in our stove collections, and succeeds with the ordinary management.

ROXBURGHIA (Jones). An East Indian climbing plant, bearing some resemblance to the *Gloriosa superba*, hence it is named *R. gloriosoides*. It belongs to the eighth class of Linneus, and to the natural order *Asphodelææ*, increased by division.

RUBIACEÆ. A large natural order containing seventy-three genera, and above three hundred and eighty-seven species. The order is divided into nine sections under the following titles, viz., *Guettardææ*, *Hameliacææ*, *Cinchonææ*, *Cephalanthææ*, *Hedyotidææ*, *Coffeacææ*, *Spermacocææ*, and *Galeææ*. The *Rubiaceææ*, collectively considered, are herbaceous plants, with square or angled stems, and whorled exstipulate leaves; the verticilli being formed of two opposite gemmiferous leaves, with a variable number of intermediate ones, not varying in appearance from the general foliage, but destitute of buds; hence being stipulaceous, and supplying the place of the interpetiolar stipules of the *Cinchonacææ*. The inflorescence is paniculate, the flowers small, and in general united. The calyx is superior, the tube joined to the germen, and the limb from four to six-clefted; the corolla is synpetalous, rotate, or funnel-shaped, regular, with its petals equal to the sepals, and exerted from the calyx; the stamens are equal in number to the lobes of the corolla, and exerted alternately with them; the filaments are free, the anthers incumbent two-celled and open longitudinally; the germen consists of two connate carpels, invested by the adherent tube of the calyx; the styles two, and the stigma headed. The roots of the *Rubiaceææ* often contain a large quantity of colouring matter. This is especially abundant in the madders, and several species of *Galium*. Madder is not much grown in this country, although the climate is suitable, because the imported madder is cheaper. Cattle fed on several of these plants have their secretions tinged with the colouring matter.

There are many beautiful as well as useful plants comprised in this order; of the first we may notice the *Gardenia*, *Isora*, and *Portlandia*; of the second the *Cinchona*, jesuit's bark, as a medicine, and the coffee as an article of diet, as examples; although these are associated with many unemployed plants.

RUBY. This beautiful mineral is, in fact, but a peculiar modification of *corundum*. Next to the dia-

mond, it is the most valuable of the precious stones. The most highly prized varieties are the crimson and carmine-red. These gems are generally found in alluvial deposits, especially in Ceylon and Pegu; those from the former place being of a pale colour.

RUDBECKIA (Linnæus). A genus of ornamental herbs, chiefly natives of America. It belongs to the *Heliantheæ* section of the natural order *Compositæ*. The flowers of several of the species are showy, and are fitting to be planted in shrubberies, or among the larger growths of the flower garden.

RUMEX (Linnæus). An extensive genus of herbaceous plants, mostly natives of Europe. It belongs to *Polygonaceæ*. The various kinds of docks and sorrels are well known plants, some few of which are cultivated, either for medical purposes or as pot-herbs.

RUMINANTIA. Those mammalia that chew the cud. See **MAMMALIA**.

RUSCUS (Linnæus). A genus of low evergreen shrubs, belonging to *Smilacææ*. The undershrub sorts are hardy and common in our ornamental plantations, and called butcher's-broom. Their foliage is remarkable, inasmuch as leaflets are borne on the disk of the larger leaves. There are three or four species which are climbers from South Africa: they are all propagated from suckers.

RUTACEÆ. A natural order containing thirty-seven genera, and one hundred and sixty-two species already described. They are an interesting, though a heterogeneous group, natives of all countries and all situations. The type of the order is the common garden rue, one of the most disagreeable scented plants; and with it are associated both shrubby and arborescent plants. They have all opposite or alternate leaves, with or without stipules, and for the most part punctate. The inflorescence is variable, either axillary or terminal, and solitary or aggregate; the flowers regular or irregular, and in general united. The calyx is formed of from three to five sepals; the corolla of five petals; the stamens are from five to ten, some of which are occasionally abortive; the disk is sometimes dilated and sometimes absent; the germen is formed of from three to five carpels, discrete or conjoined; the cells usually two-celled; the styles free or connate, and the stigmas simple or dilated. The fruit is most frequently capsular, the seeds are from abortion less in number than the ovules, with usually a crustaceous or membranous testa.

The genera here connected are divided into four tribes, viz., *Rutææ*, *Diosmeææ*, of which last there are three sections, *Cusparicææ* and *Xanthoxyleææ*. Most of these are strong-scented plants, and several of them are medicinal, especially the *Guaiacum*; and the wood of *G. officinale* yields the timber called *lignum vitæ*, so useful to turners and cabinet-makers. The common rue, formerly so much extolled for its great and various virtues, is now almost neglected, except by village doctresses.

The *Diosmas* are all favourite greenhouse plants, and easy of cultivation.

RUTELIDÆ (Mac Leay). A family of very splendid coleopterous insects belonging to the section *Pentamera*, and sub-section *Lamellicornes*, having the body short, rounded, and generally highly polished; the head and thorax are not armed with horns indicating the diversity of the sexes, the anterior margin of the labrum is exposed; the maxillæ are scaly, truncated, and toothed at the tips; the mesosternum is often produced in front into a strong spine; the scu-

tellum is generally large, especially in the genus *Macraspis*, the tarsal claws are often of unequal size, and the mandibles are corneous. The species are almost exclusively tropical, and inhabitants of the new world; and from the scaly structure of the maxillæ, and the terminal teeth with which they are provided (and which are similar to those of the *Melolonthidææ*), it is most probable that these insects in the perfect state feed upon leaves, as do the species of the last-mentioned family. The splendid colours also with which they are adorned, indicate them to be species which are abroad by day. The genera are *Hexodon*, *Cyclocephala*, *Chrysophora*, *Chrycina*, *Rutela*, *Pelidnota*, *Oplognathus*, *Macraspis*, *Chasmodia*, and some others recently proposed. Of these genera, the most remarkable are *Chrysophora* and *Chrycina*, in both of which the posterior legs of the males are very large and thickened, with the tibiæ curved and terminated by a strong hook. To the first of these genera belongs the splendid *Melolontha chrysochlorææ* of Latreille, figured in the Voyage of Messrs. Humboldt and Bonpland, and subsequently in Mr. Griffith's Animal Kingdom, and the Naturalists' Library, Beetles, pl. 14. Like the common cockchafer, this species lives in society, and was sometimes observed in great numbers by the distinguished voyagers above named. It has been generally supposed, Latr. (*Règne Animal*, v. p. 552), that the extraordinary insect figured by Shaw under the name of *Scarabæus macropus* (a copy of which is here given), belonged to the same

genus as the former; but the writer hereof having been favoured with a sight of a specimen of this very rare insect recently obtained by J. G. Childern, Esq., is enabled to state that it belongs to Mr. Kirby's genus *Chrycina*, which was established upon the inspection of females alone.

The genus *Rutela*, Latreille, is rather numerous, and is distinguished by having the legs of equal size in both sexes; the scutellum small, the mesosternum not reaching the base of the fore legs, and the body oval.

RYE is the *Secale cereale* of Linnæus, one of our cultivated cereals, belonging to the *Graminæææ*, and extensively cultivated both in the north and south of Europe as bread corn. In Britain it is but partially cultivated, and then only for gingerbread bakers and as early spring food for cattle, or for the straw of which mattresses and straw-hats and, bonnets are made.

SABAL (Adanson). A genus of palms, natives of the tropics. Some of them are lofty trees, and one of them, the *Palmetto*, is perhaps the smallest of all

the tribe. They grow well in our stoves, and sometimes throw up a sucker by which they are increased.

SABBATIA (Adanson). A genus of biennial herbs, natives of North America. The flowers are pentandrous, and the genus belongs to *Gentianeæ*. These are desirable plants, and can only be increased by seeds sown in a damp peat-earth border.

SACCHARUM (Linneus). An important genus, belonging to the *Gramineæ*. The sugar-cane has been long celebrated for its invaluable juice, and cultivated in every latitude warm enough for the nature of the plant. It is extraordinary, says a late writer, that so fine a grass, possessed of such remarkable properties, should have been unknown to the ancients, or so little sought after by them when they procured so many luxuries from the East. Galen and Pliny both mention a sweet salt which they call *Saccharum*, and which was then only used in medicine. Until a comparatively modern epoch, its chief use was as a febrifuge, a small piece being recommended to be placed on the tongue to relieve the thirst of fever. In the tenth century sugar was first substituted for honey in medicine. Like many other medicines, it has escaped from the apothecary's store, and from being dreaded as a drug, is now esteemed a luxury, or rather a necessary of life. The consumption of sugar by the British population is estimated at about a quarter of a hundred weight per annum for each person.

SAFFRON is the *Crocus sativus* of Linnæus, the stigmas of which, when collected, are the drug so called. No part but the stigmas should be prepared, and hence the number of plants required to produce even an ounce will sufficiently account for the high price this drug bears in the market. Saffron is aromatic and stimulant, and is a favourite carminative; it is, however, chiefly now valued for its colouring matter. The plants are grown in large quantities in some parts of England, and are much higher priced than those of foreign growth. The chief saffron gardens are at Walden in Essex, hence called Saffron Walden.

SAGITTARIA (Linneus). A genus of aquatic herbs, natives of many different parts of the world, and so called from the shape of the leaves resembling arrow-heads. The flowers are monœcious, and the genus belongs to the natural order *Alismaceæ*. None of the species are cultivated.

SAGUS (Gærtner). An East Indian tree, belonging to *Palma*, commonly called the sago-palm, from which the medical or dietetic substance called sago is extracted. This substance is the granulated pith of the tree.

SAINFOIN is the *Onobrychis sativa* of Tournefort, an agricultural plant, cultivated in chalky districts as a forage and pasture plant. The *Astragalus onobrychis* of Linnæus is also called sainfoin.

ST. JOHN'S WORT is the *Hypericum quadrangulum* of Linnæus, a British plant found in moist meadows.

SALAMANDER (*Salamandra*). A genus of batrachian reptiles, having some slight resemblance to the lizards in its external shape, and accordingly classed with them by some of the earlier naturalists, but very properly separated since the structure came to be better understood. The general characters may be described as follows: the body lengthened, with four feet of equal dimensions, and a long tail; the head is flat, and the ear entirely embedded in the flesh, and without any distinct tympanum, and only

a small cartilaginous plate on the opening; both jaws are furnished with numerous small teeth, and there are two parallel rows of such teeth along the bones in the upper part of the mouth, which represent the vomer; the ribs are merely rudimental, though they are not wholly wanting as in the frogs, but there is no sternum of bone; the pelvis is very imperfectly developed, and suspended to the spine by ligaments; the legs are of nearly equal length, and without any webs to the toes or claws on them, and there are always four toes on the fore feet, and, generally speaking, five on the hind ones. In the adult state they breathe in the same manner as tortoises and frogs; but in their early state they breathe in the water by means of gills. These gills are formed into tufts upon arches of cartilage attached to the bone of the tongue, and some of them retain these arches, in part at least, after they have ceased to breathe with the gills. There is a sort of membranous lid to the opening; but the tufts of the gills hang free, instead of being enclosed by any membrane. In their transformation the fore legs are earlier formed than the hind ones, and the toes are successively developed as if the one pushed out the other.

Salamanders are usually divided into land species and water species, but the division is not very precise, for the land ones inhabit humid places, and the aquatic ones breathe air, and are not wholly confined to the water. There are, however, distinctions between them, which are of importance, but which we can notice with more advantage afterwards.

Though among the humblest, least developed, and apparently least sentient of all the vertebrated animals, whether inhabiting the land or the water, the salamanders have been much famed in story for their powers of mischief and their tenacity of life under circumstances the most remarkable. There is scarcely a cottage in the country which has been visited by knowledge in any shape, where the salamander is not believed to be a creature which not only can live, but actually does habitually live, in the fire. Not only this, but where a little speculation is added to the mere report, it is said that the salamander is bred only in the fire, and especially in the long continued heat of powerful furnaces. We have heard it stated again and again, as matter of terror to a whole district, that the fires of glass-houses and other works requiring great and continued heat, had been kept so long burning, and burning with so much intensity, that salamanders had actually bred in them, and that the terrified owners had built up all the openings, so that the terrific reptiles might perish in the smouldering extinguishment of their burning cradles, instead of issuing forth to spread pestilence and death over the whole country. We need hardly say that this is not true, but still it is believed by many; and the fable has been so much interwoven with story and with song, and so much emblazoned among the nonsensical representations of the heralds, that the getting rid of it from the public mind will be no such easy matter, as those who are convinced of its absurdity may be apt to suppose. Pliny, to whom we are indebted for more of the nonsense of natural history, than we are perhaps to any other man, has tended much to perpetuate this ridiculous fable. We do not say that he invented the story of the salamander, or any other of the ridiculous stories of which his works are so full. Pliny was a mere compiler, and as such he was a pipe for trans-fusing the nonsense of others, just as is the case with

many of our modern compilers, and not a spring pouring forth its own waters of folly. But, as is the case to this day with compilers of facts and statements in natural history, who do not understand, and, therefore cannot appreciate the science of the subject, he appears to have had the stronger desire that a statement should be true, the more widely that it differed from common observation and experience. He gravely says, that by passing over and possessing the whole vegetation, a single salamander could speedily exterminate nations: now as we shall see afterwards, the salamander spends the greater part of its time in a state of perfect repose; that when it does move, its motions are very slow, and the space to which they are confined is exceedingly limited, and that, in short, the supposed poisonous exudation of its skin, by means of which it is said to have triumphed over the utmost intensity of fires, and extinguished all other kinds of life over extensive districts, is really nothing more than a very simple means of defence given to it against such enemies as attack so helpless a creature in its humble abodes.

It is generally understood, that the principal fables related of the salamander had their origin in the fertile imaginations of the ancient Greeks—imagination which produced flowers in great abundance, and often of exquisite beauty, but of which the fruit was scanty and of most inferior quality. It was a habit with them to erect every thing of which they understood but little, either into a god or a devil, according as the multiplication of the one or the other happened to be more fashionable; and of course the salamander, all fire-proof as it was, was the very best subject that could be imagined for making a devil of; we may add, that it would have answered just as well with those modern *Hadestical* theorists, who will be satisfied with nothing short of material fire and substantial brimstone, as fitting instruments of torture for immaterial and immortal spirits. This fable is a more gross as well as a more mischievous absurdity than that of the salamander, though perhaps it has the same origin. It may not be amiss to remark in passing, that the allusions to the burnings of Tophet and Gehenna, which are drawn from the Old Testament, are all made to the burning of dead bodies, or of children or other victims who were burned alive in the horrid sacrifices to the Syrian idols. There is little doubt that these were subsequently mixed up with much of Grecian fable; and that the salamander has its share in those ridiculous and most unholy doctrines which still continue to be preached up for the purpose of terrifying the ignorant.

The belief in the marvellous accounts of the salamander is now, however, in a great measure confined to those visionaries; because the dissections of the anatomists and the reasonings of the physiologists have established the proper place of the animal in nature, and proved how helpless and how perfectly harmless a thing it is, notwithstanding all that has been said concerning it. They have thus spoiled quackery, both physical and metaphysical, of what was once one of its most powerful engines. Quackery invariably laid hold of every thing that really was, or could by artifice be, made an object of terror or any other strong emotion to the multitude. If it had deadly power to any extent, it was sure to have healing power to the same extent imputed to it. Accordingly the salamander was described as being capable of extinguishing the most violent conflagra-

tions; so much so, that a basket full of salamanders would have quenched Etna itself. Its medical virtues were equally wonderful, and the most burning malady with which human nature could be assailed, vanished at the presence of the all-potent salamander. These and many other stories equally marvellous and ridiculous, have vanished before the light of modern science; and the salamander may be considered as now belonging only to natural history, and of no value or interest in any other respect or point of view.

Some naturalists consider the land and the water salamanders as separate genera or subgenera; and they appear to be justified in this view on account of the structure, the physiology, and the habits of the animals. The land ones, which are the proper salamanders, as being those upon which the ancient fables were founded, retain the name *salamander*, and *triton* is given to the aquatic ones. We shall consider them separately; but though there are several species of each division, their manners are so obscure and void of popular interest, that one or two of each will be sufficient.

LAND SALAMANDERS (*Salamandra*). These in their perfect state have the tail round, and not at all adapted for swimming. They are ovoviviparous, or bring their eggs to maturity internally, but the young are dropped in the water, and pass their tadpole state in that element; but this state is much shorter in them than it is in those oviparous *Batrachia*, the eggs of which are hatched in the water. They are found in various parts of Europe, of Asia, and of North America, but never in either of the extremes of climate, and they live in great seclusion. The American ones are more numerous than those of the eastern continent, but they are less known. They are said to want the two glands on the sides of the nape similar to those in toads, which are found in the European species.

COMMON SALAMANDER (*S. maculosa*). This species is black, marked with large yellow spots rather bright in the colour. On the sides there are ranges of tubercles, from which, when the creature is alarmed, it ejects a milky fluid to the distance of several inches. This fluid has an offensive smell and an acrid taste, and is understood to be very annoying, if not deadly, to weak animals; but it is not a poison to animals of any considerable size. It is subject to considerable varieties of size and also of colour. Its abodes are all of the most solitary and gloomy character. In the moist earth, and in tufts of vegetation by the margins of marshy pools in upland woods, in holes of the earth under stones, in ruined buildings, and in all places which have a moderate temperature and are damp. The greater part of its time is spent under ground, and it never comes abroad in the sun during summer, while in winter it remains under ground in a state of unbroken repose; and when they are in this state, there are not unfrequently numbers of them twined together. Its movement is very slow and heavy; and, instead of being courageous which the fables represent it to be, it is passive almost to stupidity, neither facing danger nor flying from it, but discharging its acrid fluid in cases of necessity. Its food consists of flies, worms, small mollusca, and other little animals, and sometimes it is said even of mud; and as it attacks, and can attack, no animal of any considerable size, it is said to be in itself free from attacks, as the other animals which frequent the same haunt with it are said to partake in that aversion in which it is held by human beings.

It does not appear to have any voice, at all events it utters no cry, and indeed it has very little of the action possessed by ordinary land animals. Though the young inhabit the water for a short time, the mature animals are very impatient of that element. When put into water, it makes more vigorous attempts to get out than it seems capable of upon any other occasion; and if it is prevented from getting out, it rises much more frequently to breathe than would be supposed of an animal in which the development of life seems so imperfect, and its action so languid.

The seat of greatest sensibility in the salamander appears to be the skin; for all the rest of it partakes of that endurance which is common to the cold-blooded animals. It is not easily killed by mechanical means, but the application of almost any stimulus to the skin affects it powerfully. Vinegar or salt throws it into convulsions; and extremes of heat and cold, or of drought and moisture, appear to be equally annoying to it. The specific effect of these is not well ascertained; but that they affect the animal more than it is affected by any thing else is certain, because it bears equally ill the opposite extremes of season and of climate, both of which send it to its hiding places, and both perhaps, when pushed to great lengths, render it inactive.

In many respects the genus differ from all other animals; and though they are still pretty generally distributed, though but rarely seen, they really seem to be creatures fitted for a different state of the economy of the earth's surface from that which now exists. There are many peculiarities in their structure, and not the least remarkable is the extreme smallness of the brain, the diameter of which is really less than that of the spinal marrow; this last consists of two distinct chords, in the one of which the extreme sensibility of the skin is perhaps concentrated, and probably the muscular energy of the body in the other. The smallness of the brain, as a definite part of the nervous centre or foundation of the animal, is a strong corroboration of the generally supposed and nearly demonstrated hypothesis that the brain of an animal is always well formed in proportion as the organs of the localised senses are well developed, and of equal acuteness. One sense may be pretty keen, though the brain is small; but we believe there is scarcely an instance of an animal with a very small brain being perfect in all those senses which have their organs situated in the head. When we speak of senses which have particular organs, the eye is the one which claims our first and chief attention. In the salamander the eye is very different from that of land animals generally, and even from those of toads and frogs. Though much less aquatic in its habits than the frog, and though understood to have passed through its transformations before it is committed to the water by its parent, for the brief period that it remains in that element, the eye of the salamander bears a very striking resemblance to that of a fish. The ball is so fixed as that it cannot turn, and the skin completely covers the eye so that only the corner is visible. Of course, there is no lachrymal apparatus, the eye having no use for tears to wash, as it is covered by the undivided though transparent skin. The cornea is very transparent, but the coats of the eye are irregular in their thickness and form, and the central part of the crystalline lens, which is albuminous, hardens by boiling like that of a fish.

The organs of hearing bear a considerable resem-

blance in their general structure to those of the cartilaginous fishes with fixed gills; and it is not a little remarkable that an animal which, in its adult state, is very impatient of water, and which spends but little of its early life in that element, should have so many points of resemblance to the fishes. Below the skin and the muscles, there is a cartilaginous operculum to the ear of a rhomboidal shape. Within this there is a cavity lined with a greyish pulp, and containing a rudiment of a tympanal bone, but no definite tympanum. Within this there are cavities and labyrinths; but still the ear is a very imperfect one. The organ of smell appears to be the best developed, the nostrils are far apart from each other, and their conical tubes are pretty copiously supplied with nerves. The tongue is short and thick, having but little motion, and copiously supplied with a mucous secretion; but it is not understood that the sense of taste is very acute. The teeth are prehensile only, and not at all adapted for bruising or dividing the food. Little further is known of the sense of what is usually called touch than the extreme sensibility of the skin, and the muscular sense cannot be very strong in so dull an animal.

The form of the skull is nearly that of a cylinder, enlarged in the anterior part, and with two lateral projections which contain the ears. The bones of the head present many peculiarities, but they are not susceptible of popular description. The posterior part of the skull has two condyles, with the hole for the spinal marrow between them; and they are fitted to two cavities in the first vertebra of the spine. The vertebrae have their posterior surfaces convex. There are fourteen from the skull to the sacrum, and a variable number in the tail, often more than double that in the other parts. The spinous processes are a mere crest, and no part of the body is so formed as to admit of any powerful motion. The pelvis is suspended by cartilages to the fifteenth or sixteenth vertebra, but there is in no instance any bony connexion between this part and the spine, so that the hind legs have but little firmness. The articulation of the fore leg at the shoulder is supported by three bones, but they are so closely united as to seem only one. The blade-bone ascends toward the spine, and the coracoid-bone and the clavicle, united by a suture, are directed downwards. The glenoid cavity for receiving the head of the humerus is on the posterior edge, so that the joint is badly situated as well as badly supported for motion, and it is confined within a limited range by processes. There are two bones in the fore arm, the one placed over the other; five bones and two cartilages in the wrist; and four in the metacarpus. The first toe has only one phalanx of bone, the second and fourth two, and the third three. Altogether, the bones of the fore feet are very imperfect. The bones of the hind feet are better made out in some parts; but the connexion with the spine is loose, and they are capable of only very slow motion. The head of the femur or thigh-bone is oval, and therefore has its principal motion in one plane only; and there are processes to stop its motions much in the same way as in the articulation of the shoulder; the under extremity of it is flattened and broad. Both the tibia and the fibula are thick and strong, though the former rather tapers toward its lower extremity, and is longer than the other. The tarsus consists of nine bones, and the metatarsus of five, and this is the part which is so

much more perfect in the skeleton than the corresponding part of the fore leg. The skin is of a leathery consistency, firm but smooth, with the epidermis semitransparent.

There can hardly be said to be any distinct gullet in this very singular animal. From the anterior part of the canal there is a gradual widening to a sort of spindle-shaped stomach, which is simple, and copiously supplied with glands or follicles which pour out a mucous kind of secretion, but little is known of the rate at which digestion goes on, though from the sluggish character of all the other actions of the animal it is supposed to be very slow. No provision can be said to be made for its hibernating as is known to be done in many other animals, by the depositing of fatty matter in the cellular tissue; but there are certain oily accumulations of a yellow colour in various parts of its body, which, by some, are considered as answering this purpose, though the fact of their doing so is not fully established.

The breathing apparatus, in the full-grown salamander, consists of lungs narrowed at the fore part, and rather enlarged backwards. The entrance to them is by a trachea of no great length, and their substance consists of cells, not of very large size, and partially divided by partitions, the vessels in which the blood receives the action of the air being ramified all over the partitions and the walls of the cells. The heart is a true batrachian one, consisting of a single ventricle and a single auricle, and it is enclosed in a proper pericardium. The heart is of a red colour. One large vessel, which brings the blood from the lungs to the heart, partakes of many of the characters of a vein; but the other trunk, which carries it from the heart all over the body, has much more the character of an artery. Taking it altogether, this is one of the most singular animals in the whole range of the animal kingdom, and a very intimate acquaintance with the animal economy is necessary for enabling one to understand and appreciate its character. The mode of its reproduction is not the least singular part of its economy. There can be no doubt that the impregnation of the ova is internal, which is not usual among the *Batrachia*; but the most curious part of the matter is that the young are understood to remain in the oviduct not only till they come out of the egg, but till they have performed all their elementary transformations, lost their gills, and are no longer proper tenants of the water, in which, however, they are understood still to continue for some short time, of course rising to the surface to breathe air whenever that operation is necessary. The common salamander is the largest of the European species or varieties, for their manners are so obscure that it is not easy, in every case, to say whether the distinction should be regarded in the one way or in the other. This one is sometimes met with as much as eight inches in length; but, we believe, very seldom more and generally less. It is quite unknown in the British islands; and is found about the middle latitudes of continental Europe, or rather perhaps in those more to the south, but in the upland districts rather than the low and warm ones. We mentioned that its colour is black, with yellow spots; but the black is true only of the upper part, the under being more or less of a bluish tinge; and the yellow spots are placed in a pretty regular row along each side.

There are, however, several other species, or at all events varieties. One of these, the black salamander

of Laurenti, is rare in France, in some parts of which the one that we have noticed is not uncommon, although, from its habits, it is but rarely seen in proportion to the numbers in which it actually exists. It is, however, by no means rare in some of the mountainous parts of the south of Germany. It is only about half the size of the common one; wholly black on the upper part, without any rows of yellow spots on the sides, and yellowish altogether on the under part. Another, the spectacled salamander, is found in the Apennines. It is a small species, with only four toes on the hind feet as well as on the fore. It is wholly black on the upper part, and yellow spotted with black on the under, with a yellow band across and surrounding the eyes, from which it gets the epithet of spectacled. Another, called the dark or funereal salamander, is found further south in Europe, chiefly in Spain, and in the warmest parts of that country. It is shorter than the common salamander, but proportionally thicker in the body and more slender in the tail. It is dark brown on the back, paler on the sides, and passing into sand colour on the under part. It frequents the margins of the water, even in the hottest parts of Spain, as for instance in the beautiful plains of Andalusia. It remains in perfect concealment all the day, coming abroad only at night, and appearing in the houses of the people, especially where they have fires; for, though it cannot bear the glare of day-light, it is fond of heat. Another species still is common in some parts of the extreme south of France. It is called the variegated salamander. It has a line of bright or orange red along the back and the tail, and sometimes lines of the same colour along the sides. The upper part and the head are of a dull green, which varies in the shade in different specimens; and these parts are in general roughened by a sort of warts or tubercles. The flanks are greyish-black, and the under parts are reddish and quite smooth or free from tubercles. It is found about the sides of ditches, and in the damp meadows which are overshadowed by trees.

In the other parts of the eastern continent it is probable that there are more species, or at all events varieties. Some have been observed in the Japan isles, principally, we believe, in Nippon, where they have acquired at least some part of the celebrity which was enjoyed by the salamanders of Europe in ancient times. It does not appear that the Japanese, who are rather a sensible people in many respects, have connected these salamanders with any fire-proof quality, or that they have supposed them to be in any way conducive to the healing of burning fevers and other violent diseases; but they consider that not only the recent flesh, but the dried bodies, have potent medicinal virtues; and, accordingly, they are in much requisition by the apothecaries; and are supposed to have similar corroborative qualities to those which are attributed to the skinks, which appear to have just as much truth in the one case as in the other. In all these species it does not, however, appear that there are any differences of habit, which can be made the basis of any thing like useful popular description.

It is the same with the terrestrial salamanders of America. So far as has been observed, these are confined to the northern parts of that continent, though not to the regions of extreme cold. They appear, as is the case with the whole or the greater

part of the native animals of that quarter of the world, to be totally different from those of the eastern continent; but in what they differ has been so very vaguely ascertained, that it is quite impossible to say any thing about the matter that could be interesting to any ordinary reader; and therefore we shall not enlarge upon them.

There is, however, one animal, a native of many parts of the British islands, and by no means a rare one, though, from its retired habits, not often seen, of which some notice appears to be necessary, the more so that its place in the systematic arrangement of animals is by no means clearly established. This is the common *land newt* or *eft*, a very pretty and very harmless little creature, though, like the salamander, it has a sort of "Cain's mark" upon it, and whoever meets it thinks he does service in slaying it. It is found chiefly in dark and rather moist places, under stones and rubbish, or in other situations of concealment. It is seldom met with above four inches in length, and it is usually of smaller dimensions. The upper part of it is yellowish-brown with dusky spots and lines, and the under part reddish with dark spots. The skin has a peculiarly delicate appearance, and the animal altogether appears to be as perfectly harmless as one can well suppose an animal to be. It does not appear that the skin exudes any acrid matter like that of the real salamander, and it cannot bite or inflict any injury whatever.

The place of this animal in the system has not been very clearly established; and indeed it is somewhat singular, that an animal which is so common should be so imperfectly understood. The older writers, as a matter of course, classed it with the lizards, as they did every reptile that had four feet and a tail; and more modern ones have classed it with the water newts, which are *tritons*, according to the proper distinctions of the two branches of the salamander family. As far, however, as its habits are known, they would lead us to place it with the land salamanders. It is, though a smaller animal than these, a much more handsome and active one; but its places of abode and its habits, so far as these are known, are exactly the same. Though usually seen about damp cellars and outhouses, the shade and not the damp appears to be that which it prefers; for it is to be met with under stones and rubbish in places which are very dry, and no one has ever found it in the water in any stage of its existence. If put into water, it shows the same impatience of that liquid as is shown by the salamander; and, though it is sometimes found in places which are very damp, the water does not adhere to its skin, but stands upon it in drops, or runs off without leaving any impression. This is not the case with the naked skin of any animal whose habit is decidedly aquatic. The greater part of these, if not the whole of them, have the skin protected from the action of the water; but it is always by a mucous secretion, and not by any merely repellent power in the epidermis, such as there evidently is in the common land newt or eft.

The manner in which this singular creature is reproduced is not known; and this is the chief point which wants clearing up before it can be fully settled whether it is to be classed with the land salamanders or with the tritons. The analogies, so far as they go, would lead us to conclude that it belongs to the former, and that it is an ovoviviparous reptile; but in such a case the analogy of habit is hardly sufficient.

This, however, is certainly the probability; and though nothing definite about the reproduction is known, there is another means by which some light might be thrown upon the true nature of the animal. We believe it is a general, if not a universal, law that the members of oviparous reptiles, especially those which pass through a tadpole state, are produced again after they have been destroyed by accident; and that those of ovoviviparous ones are not so readily restored, or rather not restored at all. In this we believe the water newts follow the same law as the water salamanders; and if it is found that the land newt follows the law of the land salamanders, then the classification may be held as established upon sufficient physiological grounds. At present, however, even this is not settled; and thus the newt remains a puzzle in natural history.

It is also a creature which is looked upon with great suspicion. It is not accused of poisoning, biting, or doing any mechanical harm; but it is alleged to be very fond of creeping down the throats of people when they fall asleep near the places which it frequents. Not only this, but it is supposed that the germ of the newt is often swallowed along with water; and that, coming to maturity in the stomach, it gives rise to the most terrible maladies. In remote parts of the country, we have often heard of fearful suffering, well understood, as the people thought, to proceed from the horrible calamity of swallowing a newt. We never indeed heard of any living newt being found in the interior of a single human body upon dissection; but the people to whom we allude looked upon dissection, for whatever purpose it might be performed, with at least as much horror as they did upon newts.

AQUATIC SALAMANDERS (*Tritons*). These have a general resemblance to the land ones in their form, though in them the tail is adapted for being a swimming instrument, which is prevented in the others by its round shape and its limited power of motion. In their physiology, however, as well as in their habits, they differ much from the land ones. Though in the adult state they all breathe air by means of lungs, yet they are constant residents in the water. Their tails are compressed laterally like the tails of fishes, or rather of tadpoles; and they swim by working them right and left. They are chiefly found in shallow and stagnant waters, very rarely in running streams, and never in the sea. They chiefly live at the bottom, under stones, and in other hiding places; and their food is understood to consist of larvæ and very small animals. They are perfectly harmless in every sense of the word; but the same dislike is shown to them as to the land salamanders and the land newts, only they are not supposed to be fire proof.

They are oviparous, and the mode of their production bears a considerable resemblance to that of the toads. The eggs are fecundated at the time of their exclusion, and they are united together in strings or chaplets, by which means they adhere to aquatic plants, to stones, and to other substances in the water. These eggs are deposited early in the season; and in many of the species they are hatched in about fifteen days. The young have tufted gills and also claspers, by means of which they can keep their hold upon substances under the water until they acquire strength for swimming. They all remain much longer in the tadpole state than the land salamanders, which are nearly or wholly out of that state before they are

excluded. The length of time which they continue in this state varies with the species, and also with the climate and the season. In very northerly places the eggs are of course deposited at a later period than they are in warmer climates; they are also often retarded by the frosts, which congeal the eggs, but do not extinguish the principle of life in them; and when the hatching is very much protracted in this way, the animals have not length of season sufficient for carrying them through their transformations, and thus they appear with gills in the following season. This happens also in the alpine regions of warmer countries, and it has led to a multiplication of species. The cartilaginous arches which support the gills are seldom wholly obliterated in these animals; and when the gills have stood the winter, they remain for almost the whole of the ensuing summer, and partially for a much longer time. It was from one of these specimens that Laurenti of Vienna formed his genus *Proteus tritonius*, a blunder which, in the blundering translation of the *Régne Animal*, purporting to be by "Edward Griffith, F.L.S., and others," has been charged against Linnæus instead of Laurenti, though the latter was without doubt the originator of it.

One cannot absolutely say that the water salamanders are more obedient to the influence of natural causes than the land ones, because the skins of the latter are sensible in a very high degree. The aquatic ones are, however, more capable of endurance than the others. They can bear to be frozen up in a solid mass of ice, and yet seem as healthy as ever when gradually thawed out. There are also few animals, whether vertebrated or not, that have such powers of reproducing lopped members as the water salamanders. They will, in a very short time, as was proved by the experiments of Spallanzani, reproduce the same member again and again, perfect in all its bones, muscles, and vessels; and, though their organisation certainly does not rank very high among vertebrated animals, it is far more complicated than that of the crustacea which have this reproductive power.

Among these animals there are wonderful degrees of endurance of all kinds; and though they are at present not very rare in some places, they appear more decidedly to belong to a former state of things than even the land ones. We are not aware that any vestige of the remains of an extinct species of land salamander has been found in any country, but the case is different with the aquatic ones. These bones have been found in the schistose strata at Oeningen, in Germany, indicating a length of at least three feet, which is four times as much as that of any of the species now existing in Europe, or we believe anywhere else. The most curious thing about these reptiles remains, is the fact that Scheuchzer, a physician of Zurich, who published a work in 1723, should have regarded them as the remains of a human being. Such, however, is the case; and that learned person wrote a treatise, *Homo Diluvii Testis*, endeavouring to prove that the fossil bones of an animal of the very lowest of the vertebrata were really those of the very highest. At that time, however, all the great accumulations of animal and vegetable remains, wherever they happened to be found, were referred to the Deluge in the time of Noah, as stated in the book of Genesis. The parties never paused to consider whether the flood there mentioned occurred in

such a manner as to produce circumstances of this kind, or into the question of there having been human beings in Germany at the time referred to by the sacred historian, or not. But the proofs are now abundant that there is not a vestige of human remains in any one accumulation to which a general cause or a very ancient date can be assigned. The once famed fossil man has thus now quietly taken its place as nothing more than the evidence that there once existed in that part of the world an aquatic salamander of much larger size than any that now occur in the living state. This, it will be admitted, is not much information; but the refutation of error is always in itself, in so far, the establishment of truth; and it is one of the many proofs which the earth furnishes that it was fit for the habitation of very different animals, and these, for the greater part, of aquatic habits, before it was fit for the habitation of human beings. Of the living species of these singular animals not much can be said; their manners are obscure; and they appear to vary so much with age and season, and also with climate, that the specific differences are not easily made out. There appear to be several species both of Europe and of North America, but they are comparatively little understood.

THE MARBLED SALAMANDER (*T. marmorata*) is found rather plentifully in the south of France, and in some other of the warmer parts of Europe. It spends the summer in the water, or, at least, rarely appears on land at that time; but it is said to winter in holes of trees or of the earth, hibernating in a state of torpor even in the warmest places in which it is found. It grows to the length of eight or nine inches. Its skin is slightly roughened by small tubercles. Its colour, on the upper part, is dull green, with large irregular blotches of brown; and on the under part it is brown, with small speckles of white. There is a reddish line down the middle of the back; and, in the male, there is a small crest along this line marked with black spots. It does not appear, however, that this dorsal crest is permanent, or anything else than an ornament in the season of reproduction. This is described as being the least aquatic of the whole; but, though it is an animal of which specimens can be obtained without much difficulty, very little is known of its feeding or of any of its habits.

THE SPOTTED SALAMANDER (*T. alpestris*) is found in more elevated places than the preceding species, and it does not attain the same size. It is mottled with slate-colour, and brown on the upper part, and red or orange on the belly, with a row of small black spots, close to one another, along each flank. The skin in this one, as in the former, and indeed in all the aquatic salamanders, is roughened by small tubercles.

THE CRESTED SALAMANDER (*T. cristata*) has the dorsal crest on the male much larger than any of the others, but still that crest is only an appendage of the breeding season, and wears off in the course of the summer. It has the skin roughened with tubercles; is brown on the upper part, and orange on the under, both being marked with round blackish spots; and the sides have lines of small white spots. The crest of the male is high, and formed into a series of points; and in the pairing time it is of a violet colour.

THE PUNCTURATED SALAMANDER (*T. punctata*) has the skin free from tubercles. It is bright brown

on the upper part, and orange, or brownish-orange, on the under, the whole marked over with round black spots, and the head streaked with black. The crest on the dorsal line of the male of this species has a curious outline, as if it were formed into a number of lobes. The toes are flattened, and slightly margined, but they are not in the least webbed.

THE WEB-FOOTED SALAMANDER (*T. palmata*) is brown on the upper part, with lines of black and brown on the top of the head; the flanks are light brown, with spots of black; and the under parts are also light brown, but without any spots; the toes are broad, and united by membranes; the male has three small crests on the back.

These are the principal species or varieties mentioned by those who treat of the reptiles of continental Europe; but it is not known what differences of habit accompany the differences of colour or of crest. Indeed, the animals are invisible for so long a portion of the year, and they appear to be so much affected by differences of climate and locality, that no very definite conclusion respecting them can be arrived at, farther than that those which have the toes widened or webbed appear to be more exclusively aquatic than those which have them simple. In North America, which is a much more marshy country than Europe, there are many more species of these animals, but nothing is known concerning them that could be in the least degree interesting to the general reader.

None of the species or varieties hitherto mentioned are known to be inhabitants of the British islands. There are, however, two reptiles found in Britain which have been called *trilons*, and which seem to belong to the water salamanders rather than to any other genus or family. These are the water efts, or water newts, of which there are two species, the one larger than the other, and not so habitually aquatic, though never found in places so dry as those in which the land eft is sometimes met with. Their structure and mode of production are very similar to those of the water salamanders. Their bodies are elongated, and their long tails are compressed laterally, so that they work as swimming paddles in the same manner as those of the salamanders. Like the aquatic species of these, they are oviparous, and their eggs are disposed in a similar manner. The young are tadpoles, breathing with gills in their early state; and when they come to maturity the gills are absorbed, and the lungs come into action. They are not found in clear or running waters, or in the sea, but in marshes and shallow pools which are matted with aquatic plants. The young have claspers, by means of which they can adhere to these plants; but the claspers, as well as the gills, belong only to the early stage of their life, and they disappear about the same time. They are not very numerous, and they are but rarely seen in proportion to the numbers in which they really exist. They are perfectly harmless creatures, but the country people have the same aversion to them as to the land newt, and kill them wherever they are found. The draining of the ponds and marshes, and the general cleaning out of the ditches and water-courses, which form part of an improved system of agriculture, have tended much to diminish the numbers of aquatic reptiles. Both the British species have the feet formed in the same manner as those of the land newt, that is, with four toes on each of the fore feet, and five on the hind, without either webs or claws. As is the case with

the salamanders of the continent, both of these are described as lizards in many of the books, but they are true *Batrachia*.

THE WARTY EFT (*T. palustris*) is the least aquatic of the two, not being met with out of the aquatic herbage, and often lurking in that where the water has dried up. It grows to the length of six or seven inches, and is of a brownish colour above, and orange, with black spots, below. The skin is roughened by small warts or tubercles, like that of many of the water salamanders; and some have alleged that these give out an acrid liquor, but there does not appear to be any truth in the statement. The head is flattened, and the muzzle blunt, and finely variegated with yellowish white; the middle of the belly is without any tubercles; the tail is much compressed, and rather deep; and the ridge of the back and tail are furnished with a crest which is notched on the back. It is, taken in whole, rather a handsome little animal, notwithstanding the dislike in which it is held.

THE WATER EFT (*T. aquaticus*) is more abundant and more generally distributed. It is more aquatic, also, than the warty one, and often seen in clear water, though in ponds and ditches, and not in running streams. It is a smaller animal than the other, being seldom, if ever, met with larger than four inches. Its skin is nearly, or altogether, smooth, greenish-brown above, and orange below, with blackish streaks on the former, and spots of the same colour on the latter. The head is flattened, and marked by two lines of black dots, but it has none of those beautiful mottlings with yellow which are on the muzzles of the warty one. The tail is also less deep in the section, and tapers to a more slender point. This animal is viewed with even more suspicion than the warty one; for it is alleged that both human beings and domestic animals are liable to swallow the spawn along with the water which they drink; and then this terrible tormenter is seen to come to maturity in their stomachs. Now, that any vertebrated animal can live in the stomach of another is an absurdity; and that a batrachian reptile should do so is most palpably absurd. To say nothing of the suffocation from want of air, no reptile of this kind can bear a degree of heat equal to that of the interior of the human body in a state of ordinary health. We have heard of many cases, however, in which this was most firmly believed; and we have actually seen persons whom nothing would persuade that they had not a water eft in the stomach which tormented them, and rose in the throat when the stomach was empty. Such persons were, we believe, troubled with indigestion, a malady which puts more crotchets into people's heads, and is, on that account, more incurable, than almost any other that can be named. The plague of the eft is, we should suppose, not so common now as it once was; but we remember the time when, in a rural and remote part of the country, there were some persons who wandered about and picked up a tolerable living, and no small degree of rustic fame, by quacking the afflicted for this and other imaginary diseases. We have actually seen a roasted shrew prescribed and taken, in order to make the newt or eft quit its abode in the stomach; but we never heard of the expelled intruder making its exit bodily, though the patient might probably be cured, as imagination is often the best and the only cure for imaginary diseases. This

is the grand hold which medical quacks of all kinds have upon the public; and though the fashion of the quackeries changes with the times, perhaps the sum total bears a pretty constant ratio to the population; and many who would treat with ridicule the idea of swallowing a roasted shrew, in order to get a live eft out of the stomach, are in all probability believers in as great absurdities. The story told about the late Mr. Abernethy, in curing the dyspeptic lady of the dread of a spider in her stomach, is well known; and though we cannot vouch for its authenticity, it was not unworthy of that very talented and eccentric character. The lady could not get rid of the spider, of course, as there was none to get rid of; but she applied to the Doctor.—“Madam,” said he, in the usual gravity of a prescribing face, “there is only one way in which you can get rid of it, but that is sure to succeed.” The lady was all ear. “Madam, you are to go home, catch a bluebottle fly, put it in your mouth, and let it buzz there; depend upon it the spider will come up to catch the fly; then watch your time, spit them both out together, and your cure is certain.” The sequel is not given; but it is highly probable that the prescription was of that valuable kind which cures when given without being taken.

SALICARIÆ, or **LYTHRARIÆ**, a natural order of plants. See **LYTHRARIÆ**.

SALICORNIA (Linnaeus). A genus of small shrubs and herbs, chiefly natives of cold countries. Three or four of the species are natives of Britain, where they are known by the name of glasswort. They are placed in the first class and first order of Linnaeus, and belong to the natural order *Chenopodeæ*. Under the name of marsh samphire, these plants are used as spinach.

SALISBURIA (Smith). An ornamental tree, native of Japan, belonging to *Amentaceæ*. The flowers are monœcious, and it appears that the female plant is scarcely known in Europe.

SALIX (Linnaeus). A most extensive genus of trees, shrubs, and undershrubs, mostly natives of the north of Europe and America. The flowers are diœcious, and the genus belongs to *Amentaceæ*. The willow, of one kind or other, is common everywhere, and several of the sorts, as the *S. rubra*, *S. viminalis*, and others, are extensively cultivated for the basket-makers, and the *S. fragilis* and Huntingdon are preferred for fœnciug; while the *S. Babylonica*, or weeping-willow, is exceedingly ornamental. There are numerous species not yet described.

SALMON (*Salmo*, or perhaps *Salmonidæ*, the salmon family). A family of soft finned fishes with abdominal fins, and the fourth in order in Cuvier's arrangement, standing between the family of the *Silures* and that of the herrings. They are exceedingly numerous, amounting to twenty genera in the subfamily of the salmon, and one genus of another subfamily *Sternoptyræ*, which agree with the salmon in some particulars, but have the body differently shaped, and are different in geographical distribution.

The soft-finned fishes, that is, those which have the rays of the fins jointed, whether they have or have not any fins absolutely soft, are in point of numbers the most abundant of all the true fishes; and, in an economical point of view, they are the most valuable. This will be understood from the mere mention of the names of the leading families, which are salmon, herrings, cod, and flat-fish, of which if the waters

were deprived, man would sustain a greater loss than if all the rest of the finny tribes perished together. Among the other divisions and families there is a valuable fish here and there; but when we come to the four which have just been named, it is difficult to say which of them is the most valuable; and if they were all taken away, our fish markets would have but few attractions compared with what they have at present; for the staple of them all at every season of the year is one or other of these four.

In the elegance of their forms, and perhaps in the richness of their flesh, the salmon family are probably entitled to take the lead; and when we consider their habits and their geographical distribution, we are constrained to acknowledge that they are the most accessible of all fishes, and almost the only ones in which man can be said to have a property which can yield him a revenue. None of the family are, strictly speaking, pelagic fishes ranging the wide seas, and none of them resort to the banks in the distant parts. The greater number are natives of the fresh waters, even though they spend a considerable portion of the year in the sea, and not a few are permanent inhabitants of the fresh waters; but they are all inhabitants of the clear water, active and lively in their manners, and never lurking in the mud.

The capture of the salmon family thus becomes the finest sport of all fishing. It is really a “field” sport, though the objects of it are in the waters; and there is more exercise, more enjoyment of scenery, and altogether more of the elements of healthful enjoyment in fishing for the members of this family, than in the capture of animals of any other description, be they what they may; all this is very delightful in itself, and certainly it is not the less so from the consideration that the produce of it is equally savoury and healthy. The other finny tenants of the fresh waters are found chiefly in ponds and pools, or in the broad and stilly places of the stream; but the clearer the water is, and the more brisk the current, the salmon family like it all the better, and frequent it in the greatest numbers. We find perch in a dull pond, and pike in a sedgy pool or stagnant part of a river; but if we wish to have a salmon or a trout we must go to where the bank is clear, and the place both delightful and healthy.

There is something more in this than the mere consideration of fishes, whether regarded in an economical point of view, or as they afford sport to the captor. These fishes entice us to the place where health and long life is to be found, and bring us acquainted with nature in its fresh and simple beauty. There is a richness of enjoyment in it which cannot be told in words, or communicated in any other manner than by actually engaging in it, and not merely engaging in it, but doing it with enthusiasm and zest. No one can conceive but one who entirely feels it, the high degree of superiority with which one who has been accustomed to catch trout after trout, or a salmon now and then, looks upon the humble fisher for dace and gudgeons in some flat, lazy, and currentless river, which crawls along making the man who stands on the bank watching the bob of the float, ten times more dull than he would be were he engaged in the most mechanical drudgery of the workshop or the counting-house all the while.

The salmon family thus form a subject upon which one could dwell and luxuriate for a long time, and always the longer the less wearied; but as all waters

are not fit abodes for these most delightful of fishes, so all the days of our lives, and few days of those of the majority of us, cannot be spent in fishing for any one member of the salmon family, and therefore we must leave this delightful part of the subject, in order that we may inform those who cannot enter into the delightful romance of the subject, where the plain business reality is to be found.

The more characteristic members of this family of fishes are found in the cold and the temperate latitudes rather than in the warm ones. The shores of the Atlantic without the tropic, and the rivers which discharge their waters into that part of the ocean, are their head-quarters. There are, we believe, some species in the northern parts of the Pacific, and the rivers which are affluent there; they are, however, nothing either in number or in value to those which are found in the Atlantic and the Atlantic rivers, and in these the salmon improve after we pass the middle latitudes of the quadrant; and it may be said that, until we come to the absolute barrier of the ice, the farther north that we get, the salmon become the more abundant in numbers, and the better in quality. They are thus fishes not merely of the places which are most favourable to the development of the human powers, but of those in which the land is less calculated to repay in food the labour which man bestows on the cultivation of it.

Numerous as the members of the salmon family are, and different as they are from each other in size, in colour, and in various other particulars, there are still very close family resemblances among them. This is perhaps most strikingly the case in the mode of production, and in the appearance of the fry or young in their very early stages. All of them ascend the streams for the purpose of spawning, even though they spend much of the intermediate time in the sea. Those which are in so far marine in their haunts, and in finest condition when caught in the salt or the brackish water, are yet capable of living and continuing their race wholly in the fresh water. This is proved by the fact, that there are salmon in some inland waters, the falls upon which are so high as to prevent all passage of the salmon—at least all passage upwards. A positive cascade of about fourteen feet in height is a complete barrier against the upward passage. But the downward is another matter, and one respecting which we have but little positive knowledge. When the fish are ascending, they keep as near the surface of the water as they can find passage and safety. They are over the shallows near the shores, at least, if the water is deep and stilly in any part.

That they should do this is part of the instinct, or perhaps we should say, the adaptation, which brings them from the sea, or makes them ascend the streams, namely, the air, heat, and light necessary for bringing forward their eggs. This is so deeply rooted in their nature, that it impels them for many hundreds of miles, at least in some of the species; and their attempts to pass obstacles are equally wonderful. Some of the species are, however, more permanent in the same localities, and they are of course less under the influence of seasons. When a salmon approaches the shore or ascends a stream, that is not to be considered as an independent act of the animal, in the same sense as we speak of an independent action performed by a human being; but there is a great disposition to confound them, and this confounding puts an end to our

rational progress in the study of nature, by leading us away from the conclusions to which a more philosophical mode of viewing the same subjects, would speedily and easily bring us. No one who has not devoted much attention, and it is a species of attention of a painful nature, would be apt to suppose this.

The human action, when it is properly such, that is, when the plan and purpose of it are forethought inferences by the mind from experience, it is, so to express it, taken out of the general operation of physical causes, the season and the climate for instance, do not affect the formation of this plan; and they have but a partial influence on the execution of it. The will does not work to the weather any more than the weather works to the will; and, therefore, though the mere working instruments which put the purpose into execution upon matter, must be in so far affected by physical causes, the mental part is not affected in that way at all. The sun rises to the evil and the good, and the rain falls alike upon the just and the unjust, without in the least affecting their moral distinctions; and that a man is wise and good, or the reverse, is not an element which we can in any way apply to the study of the rest of nature in any one of its departments.

The animal, on the other hand, is wholly under the influence of physical causes, though these admit of division into two distinct parts, the nature of the animal, and the circumstances under which the animal is placed. These are, in some respects, opposed to each other, and it is this opposition which occasions what we may properly call the working of the animal; for if the animal were either passive to the rest of nature, or the rest of nature passive to it, there would and could be no display whatever of animal life. The adaptation of the animal and the circumstances to each other, thus becomes by far the most important part of the natural history of animals, because it is that through the means of which they can be trained, improved, or made in any way useful; different animals are of course differently obedient to, or affected by circumstances; and the degree to which they are so is the measure of the hold that we have upon them, both for knowledge and for practical use.

Perhaps there are no animals, certainly no fishes, more obedient to circumstances than the salmon family; none are more useful; none are more within the limits of our observation and management; and therefore, none are more worthy of being generally observed and studied. They have this farther to recommend them that, in all the more valuable species they are exceedingly numerous and widely distributed as British fishes. Many other genera are common and valuable fishes of our seas, but the salmon family actually dwell among us; with only this difference, that they are in the stream, and we have our most pleasant dwelling, and our most refreshing and gratifying walk, on the bank.

The members of this most valuable family of fishes are so sensitive, that we can hardly mention one variation of locality, or of the succession of seasons and weather, or the mere locality, by which they are not affected to such an extent, that superficial observers would be apt to regard them as distinct species. This has led to a very needless, and indeed mischievous multiplication of species and varieties, when the whole was explainable by differences, and these often apparently very slight, in the circumstances of their localities.

The water in which they live is of course one of the circumstances by which they are affected the most, and the differences which affect them may be the temperature of the water, the substances which it holds in solution, or the food which it supplies. Those which have seasonally free access to the sea, have of course a more constant uniformity in the state of their dwelling there than those which are confined to the inland waters. But still there are differences in the appearance of the salmon even of rivers which flow into the sea at no great distance from each other. Thus in the case of the rivers of Scotland, one might be perhaps prepared to find differences in those of two great estuaries like the Forth and the Tay, which are separated from each other by a whole country. But this is not all; for the fishermen can readily tell from which of the smaller salmon rivers which fall into these estuaries, a fish comes. It is a general law that the nearer to the open sea the mouth of the river is, the fish are the finer both in colour and in flavour; and a Tay salmon caught below Dundee is far better than one caught above Perth,—and in all rivers the farther inland the fish are obtained, they are always the worse in quality. This is still not the only difference; for the salmon of rivers which have low and warm courses and clear water, are always finer, as well as found earlier, than those in mountain ones, where the water is much tinged with peat earth. Thus, on the Fife side of the firth of Forth, a Leven salmon is better than one found at the confluence of the mountain rivers farther up the Forth. It appears to be the pure water much more than the rich country through which the river flows, which improves the character of the fish. So also, at Aberdeen, the Dee and the Don enter the sea at no great distance from each other, and the valley of the Don is richer than that of the Dee; while the Dee, from the greater purity of its water, is by much the better salmon river of the two. These facts are well known to fishermen on the rivers and also to dealers. Many more might be given, but these are sufficient for proving the point.

The alternate adaptation of those *Salmonidæ* which migrate between the sea and the river, to the salt water of the one, and the fresh water of the other, shows that they are readily obedient to circumstances. It is doubtful whether upon an instant transfer from the one to the other the animal would live, or at all events be uninjured; but some additional information is wanted before this point can be cleared up in a manner quite satisfactory. It is probable, however, that they “hang” in the brackish water for some time, both in their ascent and descent; and the probability of this is strengthened by the fact that they do not ascend the smaller streams which enter the sea abruptly, with little brackish water at their union.

Of the three species, the salmon, the bull-trout, and the sea-trout, which have this migratory habit, the salmon is certainly the most discursive, both seaward and inland; and, in Britain at least, it appears to be more generally distributed, although the others are very numerous at some places. The bull-trout is perhaps the next in point of discursiveness, at least up the rivers, though its inferiority for the table makes it less an object of interest. It is a more hardy fish than the salmon, and ascends the rivers earlier; but as it is in little demand at the great markets where so much salmon is purchased, its history is left more to naturalists, and its flesh to the country people

where it is found. The sea-trout, or the salmon-trout, as it is more correctly called, resembles the salmon more in appearance, and also in the quality of its flesh, than the bull-trout does; but it is the least discursive up the rivers of the whole, and probably does not go so far to sea, or into such deep water as the salmon. It is often found in shoals of considerable number beating about the coasts, and even in the mouths of the smaller rivers, which the salmon do not enter. But it does not ascend very far up these rivers, even where there is little or nothing to stop its progress; and thus it may be considered as more a fish of the shores and the brackish waters, than of any other locality. On these accounts it would appear to be less affected by seasons than the salmon. It is, however, a good deal affected by the character of the waters, being always in the best condition where the water is pure, and the soil from which it comes, especially on the lower part of the river, rich. On the shores of the Hebrides, especially in the sandy bays, which are generally found skirting the more fertile spots, the salmon trout is found in great abundance and of excellent quality, even where there are no streams of any consequence. In many of these places it attains considerable size, is in fine flesh both as to colour and quality, and called salmon by the inhabitants.

But the changes which are produced by differences of quality or admixture in the water, even in those species which never resort to the sea, are fully as conspicuous as those which the fresh and the salt water, and the different qualities of the latter in the several rivers, occasion. We might be prepared to expect this; because the quality of the water of a river where it falls into the sea is different from that of the inland branches of the very same river. The ultimate river, as we may call it, is a mixture of many minor waters, each partaking of the characters of the particular soil from which it comes. One may be from the mountain, a second from the moor, a third from the morass, a fourth from the grassy valley, and so on through a very great number; and the compound will partake of the nature of all of them, in the proportion in which they happen to enter into it. Then after these are all collected into the main channel, the impurities may subside there, and give very different characters to different parts of the river. All these have very decided effects upon the *Salmonidæ*, especially upon such as are permanently resident, in the appearance and colour, and also in the quality, of the flesh. If from any accident the waters become permanently foul, the *Salmonidæ* quit them sooner than any other fishes, and the salmon is the first to depart, or rather it ceases to resort to those polluted waters. The impurities of all kinds which mix with the Thames may be said to have completely banished the salmon for which that river was so celebrated in former times, and there are many other instances. A remarkable one occurred in the Ness, between Inverness and the lake where the operations on the Caledonian Canal rendered it necessary to turn the river into a partially new channel. In doing this, great part of the old channel was filled with loose gravel and sand, tinged more or less with iron, of which the curious little hills in the lower valley of the Ness are composed. This banished the salmon; and when they are once banished from any locality, they do not soon return, even though the cause which banished them should cease to operate. We might be prepared to expect this, from the fact that the salmon resort so

regularly to the same river, as to produce the river characters to which we have alluded. The grilises, or young salmon, almost invariably return to the river in which they are spawned; and it is probable that the full-grown ones return to their last spawning grounds, even though they have been driven from previous ones. The return of the fish to the ground has no connexion whatever with what we are accustomed to call memory; and its present conduct is not in any way influenced by its past feelings. The circumstances of the present moment and the present place are the only ones which influence it; and such being the case, we can see no reason why it should return to a former place, if it has once since spawned in another. The return of salmon to a river which has once been wholly deserted by them, must therefore be entirely owing to accident. It is true that they beat along the shores, until they come to the brackish water, toward which they ascend, in numbers proportioned to its quantity and its quality. Even after they have cleared the estuaries, and got into the rivers, the quality of the water will make them take one bank in preference to another. Temperature may have a good deal to do in these cases, but it will not account for the whole. They always prefer the river which comes from a lake to that which brings snow water from the mountains, at least in the early part of the season; but there are some flooding rivers, which have no lakes, in which they appear very early. The Severn is a river of this description.

There are many cases in which there appear to be three varieties of trout, or even species, if colour and quality were to be admitted as specific differences, in two small streams, and the one formed by their union. If the one branch is clear, with a fine bed, dry banks, and kindly plants on the margins of the pools, then the trout are yellow and beautifully spotted. If, on the other hand, the source is marshy, and the channel contains the coarser aquatic plants, the trout are dark-coloured and coarse, and then, when the two branches unite, the character of the fish is intermediate. All those varieties, which may be found within the space of a few miles, show how much the members of this family are modified by the waters in which they reside, and renders much caution necessary in treating of species and varieties.

Food appears also to have great influence both on their appearance and their size. The whole family are exceedingly voracious and miscellaneous in their eating, though, of course, the staple food varies with the locality. In the narrow streams the principal food is those insects and larvæ, chiefly flies, which frequent the waters in such places; and this is the kind of food which appears to agree best with the species which inhabit the streams at all seasons of the year. Where there are copses, and other shelters, for those flies near the banks, the trout are always more numerous, finer, and larger, than in places where the food must consist more of worms and mollusca, and even of small fishes; and upon trouting streams the anglers know particular spots where there is better sport in one half mile than there is in several miles either above or below.

It seems, indeed, that the rapidity with which trout grow when they get abundance of flies, is at least one of the natural causes of their ascending the small creeks and streams for the purpose of spawning. The young begin to be able to feed at the time when the flies are most numerous upon the water; and

thus the young grow so fast, that they are, even in the case of the salmon, in a condition for spawning the same year. Those which are more in the brackish water, in the shallows of the sea, or in lakes, appear to feed more upon the smaller crustacea and mollusca, and some of the other invertebrated animals of diminutive size which swarm in those parts of the water, especially at the time when the young of the migrant *Salmonidæ* resort to them. They are not, however, confined to food of this kind, for they have not the least objection to a frog, if nothing else can be had; and the author of this article has sometimes seen a small trout with a frog, too big for it to swallow, hanging partly out of its mouth.

Most of the species are exceedingly active, though they spend much of the day, if clear, in a state of repose. This great activity requires a corresponding supply of food and degree of respiration; and accordingly, the feeding and the breathing apparatus are both well developed. The teeth are not of very large size in any of the species, but they are numerous. In the trouts, which are the best supplied in this way, there are five rows of teeth in the upper part of the mouth and four in the under part. The middle row of upper teeth is on the vomer, or central bone, and extends the whole length, but the salmon have fewer teeth on this part. The next rows are on the exterior margins of the palatal bones, and extend to the point, having, in all, the shape of a horse-shoe. The remaining rows are on the maxillary bones, nearly parallel to the last mentioned, and also meeting in the front. The bones of the lower part of the mouth are so placed as to fall or lock between these when the mouth is closed. There are two rows of teeth upon the tongue, and a sort of groove between them which receives the teeth on the vomer, and the remaining teeth are on the inferior maxillary bones. All these teeth, but more especially those upon the vomer and the tongue, have their points directed a little backwards. They are all prehensile teeth, and the middle rows are more strictly swallowing teeth; but the whole armature of the mouth is such as not to miss a very small object, and to be capable of holding one of considerable size. They can swallow with great rapidity, and thus can fare well upon minute animals. Their power of swallowing is farther increased by teeth on the bones of the pharynx. Indeed, though all these teeth are prehensile, they have more of them than any other family of fishes. When the mouth is open, the lower jaw seems longer than the upper one, but it shuts with a motion obliquely backwards, so that it closes within the upper one. This motion farther assists in the operation of swallowing; and perhaps there is no animal that can swallow so often in the same time. The stomach is ample, and furnished with many cæcal appendages. The air-bladder has generally a communication with the gullet at the upper extremity. The gill-lids and flaps, upon the freedom of action in which the degree of breathing in fishes much depends, are remarkably well made out; and some of the species, the salmon especially, have more blood in proportion than many other fishes.

To enter into the details of this very abundant family would require many times the space that we can afford for this article, and even then there are great uncertainties, not only about the species, but about the genera, that have been proposed by some of the writers on the subject. This arises in great

part from that adaptation to circumstances, and modifications by them, of which we have given an account. There are some perplexities among those which are found in Britain, and these are greatly increased when we come to the continental ones. We must, therefore, confine ourselves to rather a limited enumeration, and to notices as short as possible—pre-mising that, in our language, the whole are called either salmon or trout, though the local names, even for the same species, are often many, and the local differences not few.

SALMON (*Salmo salar*). This is the fish, *par excellence*, of the whole family, and one which is exceedingly abundant. When in the very young state, it is the "smout," or "smout," the meaning of which is "little one;" when it acquires more size, it is a "grilse," or "gilse;" and when it comes to the full colour and flavour of its flesh, it is a salmon. The characters of which it partakes, in common with the rest of the genus, are: the body scaly; the head smooth; the back, with two dorsal fins, the first of which has jointed rays, and the second is a fleshy lobe; the ventral fins nearly under the first dorsal; the teeth as above stated; and the rays in the gill-flap from ten to twelve, but not constant in the same species, or both equal on the two sides of the same individual.

The form of the salmon is elegant, finely adapted for getting through the water; and, when it first comes from the sea, there is a peculiar metallic lustre on the covering of its body. This is common to it and the others which migrate, and would at once distinguish them from the species which reside constantly in the fresh water, even if there were no other differences between them. At this time the head and back are bluish black, passing gradually through lighter shades to silvery white on the belly. The dorsal, pectoral, and caudal fins, are dusky black, with the exception of the second, or fleshy dorsal, which is of the same colour as the part of the back to which it is attached. The ventral fins are white on the outer side and blackish on the inner, and the anal fin is wholly white. When they first quit the sea they have dusky spots on the sides above the lateral line, more numerous on the females than the males, but these wear off in the fresh water; and in time the lustre also decays so much, that, in their exhausted condition after spawning, they are called black fish. The teeth are short, but stout and pointed backwards, and there are seldom more than two, and often only one, on the vomer. The posterior outline of the gill-lid is more rounded than in the other species, and the lower line of it curves more upward at the rear. The dorsal fin has thirteen rays, the pectoral twelve, the ventral and anal nine each, and the caudal nineteen. In the fry the tail is rather deeply forked; in the grilse the termination is concave; and in the full-grown fish it is nearly square over. The body is long, with nearly the same curve in the upper and under parts, and the lateral line straight and widening between them. The head occupies a fifth part of their whole length, and the beginning of the dorsal fin is exactly midway between the nose and the tail, with the ventral fins under the middle part of it.

The whole economy of the salmon is highly interesting, and it has the advantage of being better known than that of almost any other fish. In noticing it, however, there must not be any very precise

reference to time, because that varies not only with the situation of the river and the season, but with different fish the same year in the same river.

They appear first in the offings and lower parts of the estuaries, the females before the males, and the grilse before the full-grown fish. The young ones, and a few of the old, are found in the lower parts of the rivers before all those of the former year have descended. At this very early time, although a few fine fish are sometimes obtained, the fishing is not judicious, because the descending fish are apt to be taken along with the others; and this is injurious to the fishery, and also the cause of unwholesome ones being sent to market. As they are then scarce, and only obtained in particular parts of the rivers, they bring a high price; and as it is fashionable to have them, and all buyers are not judges, many bad ones are disposed of; and though they are not absolutely poisonous, people often pay a high price for suffering the luxury of a salmon in bad condition. They continue to come during the summer months, and those which make their appearance in the estuaries during the summer months are always both the largest and the best. If the river is not interrupted, they ascend to a great distance from the sea pretty early, though they are always the worse the further that they "run" as it is called. If they do meet with interruptions in a river, the water of which is favourable for them, they make unwearied efforts to overcome these obstacles. When the drought is great, and the river very low, there is comparatively little stir among them; but when the rivers are swollen by rains, which is often the case in the mountain districts even in summer, they are more on the *qui vive*, springing at the breastworks of the cascades in one place, and taking higher leaps than hunters, and darting up the temporary rapids in others. Their spring is of course taken from a lateral bend of the body, the caudal fin laid flat being the starting point. Their passage up the temporary rapids is not so easily observed, as these are generally so foul and foaming that a salmon can hardly be seen, unless when it springs out of the water. There are, however, some very peculiar places of the rivers, generally about the places at which these issue from the mountains, where vast numbers of them accumulate, waiting the rising of the waters. In some of them the current has won for itself so peculiar a channel that the salmon cannot leap at the fall when the water is low. The pools at such places are often very deep, and partly under the projecting rocks. Basket-nets at the end of long poles are used for catching them at such places, and many are caught; but the fishermen sometimes fall in and get rather an unpleasant bath. When there is an insurmountable fall, not very far from the sea or a river of any size, with a large pool, they collect in great numbers, and continue their fruitless leaping for a long time, till at last they commence spawning. Rivers of this kind have salmon very abundant below the fall, large in size, and of excellent quality. Except the leaping at the breastwork, which is probably not very often tried by the same individuals, their summer labours are shorter and less violent than where they can range further up the river; and thus they can spend a longer time in the sea, the situation in which chiefly they gain both size and flesh. Where they accumulate in such numbers, they have many enemies. Otters and probably foxes, and even wild cats, attack them; and

the others are said to get so dainty in such places that they merely eat the tidbit, and leave the great bulk of the body. Man comes too with spears, and grapnels, and various other engines; and the treacherous practice of "burning the water," that is, holding a torch over it, which at once shows the salmon and bewilders them. This last operation is of course performed during the night only, and they who engage in it must lay their account with many a ducking; and besides this, the practice is illegal. By one or other of these means, many a female salmon is widowed over and over in the course of the season. The females are the suitors, and they fetch the males, one at a time, from the deep to the bank or run in which the trench for the young is to be made. The poacher (for none but a poacher would do it) spears the male, and the female goes and fetches another.

The spawning takes place in the autumn, but the time varies, though the mode is in all cases nearly the same. The pair make the furrow with their snouts, working with their heads to the stream; for though they can descend a current with ease and safety, they cannot "hang" in it with the head downwards, or the water would get under the gill-lids, entangle the gills and choke them. The time of spawning takes on the average about ten days, the large ones taking the longest time; and after it is over they go into the deep water quite exhausted. The time that the eggs remain in a state of repose varies with the river. Three months may be about the average time in Britain; but it varies with the place and season, the hatching of the eggs being produced by external causes. In consequence of this, though the eggs are deposited at very different periods of the autumn, some, in fact, in the end of summer, and others not till the beginning of winter, yet they are all hatched at the same time, that is, in the same part of the river and the same season. That this must be the case, must appear at once to any one who thinks for a moment on the subject. That the eggs should remain inactive in the bank or run in which they are deposited by the parent fishes, whether that period be three or four months, or even longer, which it is in the rivers far to the north, tends in no way to ripen or bring forward the eggs. They remain perfectly unchanged until the warmth of the ensuing season has acquired the strength necessary for stimulating them; and if that were to be delayed for a year, or for many years, an unlimited number indeed, there is no reason to suppose that their fertility would be in the least affected. There is, in fact, an *experimentum crucis*, which has been actually made, and which goes very far toward establishing the point. It is a general law of nature, to which we believe there is not one exception, that when any natural operation can be hastened by one mode of treatment, it can always be retarded by the opposite mode. Now the eggs of salmon, in their unaltered state, have been put in water, exposed to a moderate temperature, and thereby hatched in a very short time. In the natural state they do not require above three or four weeks; and perhaps the time required by artificial treatment is shorter. That, however, is not a matter required for establishing that there is no definite time by the kalendar between the depositing of the eggs by the parent salmon and the appearance of the young fry. When deposited they are wholly left to the care of general nature as a stepdame, and, of course, the time of their coming to life depends upon her. It

must not, however, be supposed that all which are in the same run, or even in the same spawning-bed, must come to maturity in the same hour, or even in the same week. The eggs are many, and they are piled upon each other, so that the heat of the season cannot act equally upon them all, and therefore it is impossible that they should all come in a moment without involving the most unphilosophical doctrine, that causes differing in power or circumstances, can produce effects exactly equal, which would be a virtual destruction of all reasoning from experience. The young salmon remain for a little time in sand and gravel, supported by the remains of the egg which still adheres to the abdomen, and not requiring any other food. But this state continues only for a few days, and then they bore their way upward and through the sand, "spring up like young onions," as we have heard a very intelligent salmon-fisher say. At this early stage they are about half an inch to an inch in length. Their earliest food, after they "come off the egg," is not very well known, but they cannot be in much want, because, by this time, the small life with which the waters swarm in such abundance, comes into its greatest activity. They grow rapidly, attaining a length of three inches during the first week or ten days. The head, and especially the eyes, are the parts first developed, and they are so large in proportion to the rest, that, according to our knowledge, an infant salmon is not handsome. This early maturity of the eyes, shows us that the young must depend chiefly on the sense of sight in finding their food. Indeed, it is the sense of the fishes through life, and it is probable that they have no other seated or local and appropriate organs which have any great degree of acuteness. That they have taste or smell, both the structure and the fact lead to show; the hearing of fishes is an obscure matter, and probably in a great degree merges in the general muscular sense of the body, which is very keen in the whole family.

The very young salmon have dusky crossbars along the sides, the same as are seen on parr; and probably the whole family have the same when very young; but they go off in the majority before these attain any considerable size. This is of some importance among systematic naturalists, who wish to be precise in species; but it is of small utility in those general views which are most interesting to the public. Granted that they all have these bars when young, and that the parr is the only species that retains them: What follows? That parr is the "typical species?" It would be difficult so to persuade any one who has seen a salmon or even a trout.

The whole matters of the migration to the spawning ground, the passiveness of the eggs during the cold season, their ready obedience to the returning heat, and all the other movements connected with the operation, are most striking instances of natural adaptation. The salmon resort to those places where their eggs are secure from destruction by the variable weather of a long spring, which would call them into life during the blink, and leave them to perish in the blast. Where they are deposited, the warm season comes late, but for that very reason they arrive at maturity sufficiently early for enabling them to maintain their ground. This is one of the reasons why the salmon is so much a fish of the cold northerly places; for though there are a few in the

there are not many, and they are chiefly in those rivers which have their sources in cold and bleak districts.

After the present fishes have performed their grand work in the general economy of the system of life, by nursing a succession of future salmon, they rest for a little in the upland pools; and then descend, first by very short stages, and never with that vigour and animation which they display in ascending. Their descent is in the winter, or the very early spring, and the very same sensibility to the weather which makes them show themselves on the ascent, by being on the shallows or near the surface, sends them into concealment on their descent. The air is then much colder than the water, and the shallows are much colder than the depths, which is the very reverse of the state of things when the fish come most abundantly into the rivers. Their food is also down in the winter, and the very early spring, and up when the season is advanced, by the very same law of nature which regulates the movements of the salmon. These descents are thus from pool to pool, and as they pass they keep the deepest parts of the channels. The fish are weak and exhausted, unable for much exertion and unwholesome as food, while they are descending; and nature harmonises with them, so that they reach the estuaries with little diminution of their numbers, compared with what they sustain on the ascent. In ascending, too, they have the current to contend with, though the fact of their keeping near the banks helps them in their ascent, by giving them the advantage of the eddies. But in descending, when they are weak they have the advantage of the deep water, and they have it the more from keeping in the stream.

These adaptations, though only part of what are to be met with in the whole of nature, have much of very pleasing instruction in them, if our limits would permit us to point it out; and probably there are few subjects of a nature so very familiar, which are better calculated to show man the advantages of his situation, and the means of turning those advantages to account, than the economy of the salmon. If all those that enter a good salmon river were to spawn there, and all the eggs were to come to maturity, there would not be room, far less food, for the young. Thus when they are in the very best condition, they come into the situations where man can most easily capture them and turn them to account as an article of merchandise. And they come so much loaded with wealth, that though nearly ninety-nine out of every hundred were to be taken, the remaining one would replace the waste more than a hundredfold. Therefore, besides the most valuable and inviting store which they offer to man, there is still a great surplus for the general purposes of nature; and there are many animals in and upon the water which would perish of want if it were not for the supply afforded them in the eggs and the fry of the salmon. We may mention one—the Dipper, which is often found on the rocks and runs of the mountain streams, caroling as blithely as a lark in the dawn of the spring, while the snow on the mountain yet remains pure and unspotted in its whiteness; but were it not for the eggs of the salmon, and other fishes of the same family, the dipper would be mute and motionless.

In this manner do the productions of nature support each other, and one race actually has its own preservation in the supporting of another; and though

man as an intellectual being cannot be said to be wholly within and under the laws of this wonderful system of physical nature, yet the system is so adapted as not only to include him as a member, but actually to measure his enjoyment in proportion as he can bring his intellectual powers to bear with rational knowledge and proper effect upon that part of the system which is wholly physical. Look at any natural production, animal or vegetable, which man has with proper knowledge of its nature, taken, we will not say under his *protection* (for protection is of a higher order), but under his management; and say, whether improvement and increase have not been the invariable results. Are there fewer sheep and oxen, because they are used largely for food, or fewer horses because they are worked in England, than there would be if they were all left to nature, and man were a naked savage in the woods? Certainly not. It is the ignorant man, who comes to the rest of nature with only his physical adaptations, as if he also were a beast, that spoils and depopulates nature: the man who acts with knowledge improves and multiplies; and wild nature partakes in the blessings of civilisation.

When the descending salmon reach the brackish water in the estuaries, which is the very time when life in that most fertile of all situations, is in the prime of its activity and abundance, they tarry for a long time, and regain their flesh and continue to increase in size. It is probable that the young of the year do not go very far below the limit of the brackish water, for they begin to ascend at an early period of the season. They are obtained of two or three pounds weight about the end of June, and much more than that in August; and they continue to furnish a supply at the time when older salmon are not fit for the market.

Perhaps the salmon go farther out to sea as they get older; but still they cannot go very far at any time. They are not pillager sea-fishes, or properly sea fishes at all,—they are fishes of the streams, the estuaries, and the shore. They are also not bottom fishes; for the soft-finned bottom fishes are formed for ascent and descent, by having the ventral fins as far forward as the pectorals; whereas all the salmon have them abdominal, and are thus formed for straightforward motion. Salmon cannot therefore go to those depths of the sea which may be regarded as the utmost limits of fertility at the bottom. The bottom fishes then all have spinous fins, generally fit for being weapons; great heads, and large eyes directed upwards, and the lateral fins concentrated on the fore part of the body. The salmon have small heads, and small eyes directed laterally; and they are but little fitted for motion in ascent or descent, although finely formed for progressive motion.

From these circumstances, or rather from the induction of those to which they lead, there may be drawn one of the most important conclusions connected with the whole economy of the sea. We have no room for the expansion of these; but the hints which we have given may render them easy to any one; and the result is this;—the salmon which are bred in a river can never go to any great distance from that river, or pass their time at very great depth in the sea. They very speedily regain their flesh in the brackish water; therefore the conclusion is, that if the habits of salmon were properly known, we might have an *uninterrupted supply of salmon, in the very best condition, all the year round.*

There remain three other very interesting subjects connected with the salmon, of which, however, we can only mention the names. First, anecdotes of salmon, some of which are very curious; secondly, the catching of salmon, many ways of which are equally so; and thirdly, the progressive history of the laws relating to salmon-fishing, in which there are to be found some of the most matchless instances of human cupidity completely caught in the net of human folly, that ever helped to render the statute-book the most splendid monument of blundering that is to be found upon earth,—we had almost added—or in the sea; but a single foot of that puts an extinguisher upon the most magnanimous of land-fools.

We have exceeded our limits, in consequence of the attractive nature of this archon of the waters; and yet we have barely begun what we could have wished to say. This is, however, the only opportunity which we shall have of “serving up a salmon” to our readers; and we could have wished it were “better done,” as underdone salmon is unwholesome. We refer the reader to Yarrell’s *admirably dressed fishes*, for a synopsis, reserving to ourselves personally a few points, and a very few, upon which we are at issue with him, notwithstanding the *recherchéness* of his *cuisinier*.

SALMON TROUT (*S. trutta*). Though this species is not entitled to rank with the salmon, either in interest or in commercial value, it is unquestionably worthy of the second place in the order of value. In colour it is not very unlike the salmon; and in many instances it passes for small salmon or grilse, and for the table it is certainly not inferior, we should say it is superior to the latter; but any one who has seen them together, can be at no loss in distinguishing them, even if they should be exactly of the same size. Besides the particular differences, of which we shall take some notice, there is a *je-ne-sais-quoi* difference which strikes one at first sight, but which it is not easy to explain in words. Upon looking at them one would at once point to the salmon and say, “This fellow is the better swimmer.” The head is more tapering; the muzzle more pointed; the body more stretched out; and the fish is better formed. The caudal fin especially, which is the grand organ in swimming, is considerably smaller, and the fleshy back which forms its base is more slender. The difference, however, is in the length of the rays rather than in their number. The caudal has the same in both; the pectoral and anal have each a ray more, and the dorsal has a ray fewer than in the salmon. The spine also has only fifty-eight vertebrae, while that of the salmon has sixty. In fact, however large and coloured like a salmon it were, if one at all acquainted with fish were to see it lying on its side, he would at once and without hesitation say, “that’s a trout;” although most likely the only explanation he could give would be, “it is more like a trout than a salmon.” The contour is not so light and elegant; the fish looks more lumpy; the colour is not so pure, either in the bluish or the silvery part; and the spots on the side are smaller, more defined, and some of them come below the lateral line. There is also a considerable difference in the posterior outline of the gill-cover, which forms a sort of parabola, not a circle as in the salmon. The scales, too, are smaller, and not so free at their hind edges. The examination of the mouth presents other differences; and leads to the conclusion that there must be some difference in the food,—that the food of the trout consists of smaller substances than that of the salmon. The teeth of

the salmon are larger in proportion; but they are less numerous in all parts of the mouth, and there are only one or two on the vomer. The vomer of the trout is toothed for a considerable part of its length; and the teeth in the other rows are closer together, though smaller. When the salmon is in the offings of the estuaries it returns with the flood to feed on the sand larmer which then comes up out of the banks, whereas the food of the trout is the sand hopper and other crustacea and mollusca which are nearer the land.

It should seem that, altogether, the salmon trout is a fish much more confined to the line between the ebb and flood, coming and going with the water, and not, at least in some places, passing to any considerable distance up the rivers. In many places it does indeed ascend the rivers; but certainly not to such a distance from the sea as the salmon, though it is more plentiful in the estuaries, on the shores, and in the lower parts of the rivers than the salmon. Its flesh is not quite so rich as that of the salmon, but it is very good, and like the other always the better the nearer the sea that it is caught. Those which are obtained in the sandy bays where there are no rivers that they can ascend to any distance, are hardly inferior to salmon of the same size; and their abundance, and the fact of their being met with at places where there are no salmon, are additional recommendations of some importance. The quantity in which they can be obtained in some of these bays is perfectly incredible to those who have not actually seen it; and the take, by one haul of the net, exceeds that of the salmon in the very best pools of the shoal rivers, where the fish are stopped by falls. Though not unknown, they are by no means very numerous, on the southern coasts of Britain; but on the west coast of Scotland, and especially among the Hebrides, and on many parts of the coast of the west Highlands, they literally swarm. On the east coast of Skye we have seen a large boat-load captured in little more than one hour; and the last haul as plentiful as the first. They were not in one bay, but in every bay; and yet on that particular part of the coast, there is no stream larger than a brook, and these are not ascendable beyond a few hundred yards; nor was there any reason to doubt their being equally numerous in all the islands where there are eddies. What may be the case now, we know not; but at that time they were but little heeded. There was no market for them in the fresh state, and nobody to eat them; and the salt duty prevented them from being cured. It was with no small trouble we could get one boat load given away, as any one who cared for them could have them fresh out of the sea when he pleased. The neglected wealth of these western seas, at the time to which we allude, was inconceivable; it may be better now; but we have doubts.

Familiar as this fish must be to all who live near the sea on the coasts where it is so plentiful, there are some mystifications in its history; for there are two, a larger fish with redder flesh found more in the estuaries, though never far from the shore, and a smaller one with the flesh still reddish, only much paler than that of the other, which is found chiefly in the lower parts of the smaller rivers, or in the tidal water immediately at their mouths. This larger is called locally the sea trout, or sometimes the red sea trout, alluding however to the colour of the flesh, not of the surface. The dusky black on the upper part has a greenish tinge, and there is a shade of purple

in the spots. In size and weight it varies considerably,—three or four pounds being about the average, though some are met with weighing fifteen or more. This one is a thick and compact fish, with the curve of the back nearly the same as that of the belly, and answering to the characters usually given to the sea-trout.

The small one is more uniform in size, at least at the same place and time, being in general about a foot long. It is thin and not nearly so much arched in the back as the large one. The upper part of the body has a greyish instead of a greenish tinge; the under part in both is white, but this one has much less of the silvery or metallic lustre, though enough to procure it the name of sea-trout, whatever other it may receive. It is found in smaller streams than the larger one; but it does not run far; and it seems to spawn earlier in the season than the other. Smaller ones are met with about the upper part of the brackish water of the streams in the earlier part of the season; and one or other may be had, not far from the same locality, all the year round, or nearly so. The form and armature of the mouth are the same as in the larger one. There are we believe sometimes differences in the number of rays in the fins; but when we find some of the salmon family with more rays on the gill-flap on the one side of the head than on the other, we must hesitate before we admit the number of rays in fins as a very definite specific character.

The small one gets different names; and these have perhaps, contributed to the erecting of it into a species which has been done. But smault, grilse, and salmon, are also different names, and yet we know that they mean only different ages of the very same fish. This is not the only assistance which the analogy of the salmon affords us here; for the habits of the whiting, as it is called in some places, or the white trout, as it is called in others, bear very nearly the same relation to those of the larger sea-trout that the manners of the grilse bear to those of the salmon. It seems, therefore, that this small fish is really nothing else than the sea-trout of the first year; and its being so is corroborated by the fact, that it is not found excepting upon places of the coast where the other is also found, only they are not both met with in the same spot, or at the same time, which is also the case with salmon and grilse. The only conclusion to which we can fairly come in the meantime therefore is, that these are only one and the same species. This is the conclusion at which Mr Yarrell arrives, from a careful comparison of this supposed species of salmon-trout of the first year.

BULL TROUT (*S. eriox*). This species, which from the colour of the upper part is also called the grey trout, is the only remaining British species which is migratory between the sea and the fresh waters. In the form of the head, the projection of the under jaw beyond the upper when the mouth is open, and in the adaptation of its form for swift and long-continued swimming, it resembles the salmon more than the sea-trout does; but still the air of it is quite different from that of the salmon. There are also some structural differences. The tail at the insertion of the fin is thicker than in either of the others; and the fish altogether seems rougher and coarser. The outline of the gill-cover is straight behind and under. The dorsal fin has a ray fewer than in the salmon trout; and the pectorals and the anal have a ray more.

The spine has a ray more than in the salmon trout, and one less than in the salmon. The teeth are rather larger than in the salmon trout, and there are not quite so many on the vomer. Along with its coarser appearance, it appears a more vigorous fish than either of the other two, and anglers find it stronger in the water. It grows to a size and weight intermediate between the salmon and salmon trout, being sometimes met with three feet in length. When of that size it weighs about twenty pounds; but specimens of such magnitude are of rare occurrence. It is not so generally distributed as the salmon trout, and is not much seen except in the rivers. In some places it is called the sea-trout, indiscriminately with the salmon trout; and the young of the year is also called the whiting. It is probable, indeed, that the small ones referred to in noticing the salmon trout may consist of a mixture of the young of both species, for externally they are very like each other; and the colours even of the adult ones, when out of the breeding season, are not very different. When they come to table, however, there is a wonderful difference between them. The flesh of the bull-trout, even when in the best condition, is only dull yellowish white, and that of the young ones is dull white. In both states it is comparatively juiceless and flavourless; and therefore it is not in such demand at the first-rate markets as to render fishing for bull-trout much a matter of commerce. Accordingly, it is left to the anglers, who find it earlier in the waters than any of the other migrants of the family; and though it is not the very best prize for the pot-fisher, it is one which affords a good deal of wholesome exercise to those who fish for sport. It has not the weight of a "prize" salmon, and thus it may not be so difficult to land; but it is more vigorous when struck, and dashes, plunges, and leaps, with so much muscular vigour, that it can be kept only by the best tackle handled in the best manner. It is, however, easily found; for it is one of the most voracious of the family, and not so wary as the common trout, which, after all, is the prince of the family for *fine* fishing. In fishing for bull-trout one does not require to be very particular as to the fly that is on the water; for fly or bait, it will bite at any thing; and so determinedly, that it can be struck without much difficulty. It also admits of stronger tackle being used than the other *Salmonides* of the rivers; and thus its voracity furnishes at least part of the means of overcoming its strength. In the breeding season, or rather preparatory to it, which is the time of blooming with fishes as well as with flowers, there is a difference in the colour of the males and the females,—the former being reddish brown on the back, and the latter dusky grey; but at other times both fade to dusky black, in which state their external colour is very like that of the salmon-trout. We believe that this species is more common in the southern or middle parts of the island than in the northern ones; and even though its flesh were of better quality, it is doubtful whether very profitable fishing for it could be established.

It is by no means improbable that the *Hucho* of the Danube and its branches may be the same as the bull-trout of this country, though there are some differences in the lateral spots, and the muzzle is said to be more pointed. There are not, however, greater differences than are known to be produced by climate in some of those members of the family with which we are more familiar. The foreign salmon are, how-

ever, in many of the species, puzzles which nobody can explain; and we have not room for the explanation, even if we could give it. The species that we have shortly described are the only migrant salmon whose history is well made out, and they are also the only ones which are of interest to the English reader.

On some parts of the continent there are said to be salmon which are cut off from all connexion with the sea, as, for instance, in the Rhine and its branches above the great fall of Schaffhausen, and also in some parts of Scandinavia, where there are cataracts near the sea. Analogy would lead us to suppose that there should be something analogous in the American lakes, and the streams which fall into them above the fall of Niagara; but these are subjects the investigation of which is difficult. It is no violence to the analogies, however, to suppose that the migrant species could live wholly either in fresh water or in salt.

COMMON TROUT (*S. fario*). This is the most common, the best known, the most varied, and, in some of its varieties, the most beautiful of all the species; and we may add, that in the pleasure which its capture affords, and the quality of its flesh, it is far from being the least valuable. It is also a fish of the most pleasing manners, if the epithet can be applied to a finned inhabitant of the water. It is a very handsomely formed creature; its motions are lively and graceful; its disposition is energetic and brave; there is more speculation in its eye than in that of most fishes; it is susceptible of education, and evinces (an animal) feeling for kindness done. To see it in the water, one would conclude that it is the most timid creature in existence; and it betakes itself so quickly to its hiding-place, upon being seen, or rather, upon seeing any one approach, that one would not fancy that it could "hurt a fly;" but, for all this apparent gentleness, the pike itself is not more voracious. It is true that the trout does not stand accused of preying upon "geese and swans," as is sometimes alleged of the pike; but the trout is the more clever fish in the water, and also the more courageous; and instances are mentioned in which the pike has been beaten off the ground by the trout.

The trout is one of the best weather-wisdoms that inhabit the streams, and shifts its ground with very slight changes of light or heat. It does bask sometimes when in a state of repose, but never in very shallow water. Nothing can surpass the quickness of its eye, or the sensibility of its muscular feeling, or that general sense of the body which seems to detect the very slightest change, or even agitation, of the water. A shadow thrown on the water, the tread of one passing along the bank, many things which a man would not notice unless he were actually looking out for them, are seen or felt by the trout. This is one of the reasons why trout-fishing is so favourite an exercise; and, as skill rather than strength is required in it, it is one which any person may take. In consequence of this, there is seldom any good trout-fishing near towns, as the waters, if open, are poached by everybody, and, if preserved, by the owner and his friends, so that but few are left, and these few appear to get wary as their companions are fished out. To give a very minute description of the common trout is unnecessary, and could not be made general, as the fishes, from their great sensibility, vary with almost every stream, and every consi-

derable difference of the soil through which the stream runs. The following, however, is about the average: the head shorter, and the nose more blunt, than in the salmon, and the eyes larger and nearer the point of the muzzle; the dorsal fin with three more rays than that of the bull trout, and all the others the same; the vertebræ only fifty-six in number; the fins larger than in the bull-trout; the teeth in all the parts of the mouth where the *Salmonide* have them, and those on the vomer extending the whole length of the bone. These characters are pretty constant, only in old males the jaws lengthen, and become curved. The colours vary much more; but the following are perhaps nearly the average in fine pure water: the upper part rich yellowish brown, clouded with darker spots of reddish brown, the ground-colour fading into bright golden yellow on the lower parts of the sides, and into delicate silvery white on the belly, but without any metallic gloss; about a dozen of bright carmine red spots along the lateral line, and a variable number of smaller ones, of the same colour, above and below; the soft fin on the back margined with bright red; the red appears to be the nuptial bloom of the fish, and gets duller at other times. In the younger ones, in very small and clear streams, the colours are paler, there are fewer of the reddish brown mottlings, and the red spots on the sides are more conspicuous. In dark waters, which contain peat or bog earth, the beauty of the colours is in a great measure lost. The back is greyish black, the flanks lead-colour, and the belly greyish white. The lateral spots on these are dull and dusky, and in some instances almost black. In the small ones, that are finely coloured, the flesh is pure white; and in the large ones it has a very slight rosy tinge, iridescent if the flakes are separated entire. The dark ones have the flesh a little greyish.

The largest and fattest trout are found in the rich places, but higher up the streams than salmon or the sea trout are found in abundance or of good quality. They prefer waters where streams and pools alternate with each other; and though they ascend to spawn and descend again, they are not very discursive. Of their size it is as difficult to speak with certainty as of their colour; and, indeed, the size of a fish stated in any other way than as a rude average of those of a particular locality, cannot be looked upon as specific. The size of the trout depends a great deal on the food which its pasture affords. As illustrative of this, we may quote a passage from Mr. Stoddart's "Art of Angling in Scotland."—"Fish," says Mr. S., "were placed in three separate tanks, one of which was supplied daily with worms (*lumbrici*, we suppose), another with live minnows, and a third with those small dark-coloured water-flies which are found moving about on the surface, under banks and sheltered places. The trout fed on worms grew slowly, and had a lean appearance; those nourished on minnows, which, it was observed, they darted at with much voracity, became much larger; while such as were fattened upon flies only, attained, in a short time, prodigious dimensions, weighing twice as much as both the others together, although the quantity of food swallowed by them was in no wise great."

In so far as finding the best fishing-ground is concerned, there is a complete angler's guide in this passage, short as it is; and it also affords a means

of judging at what season the trout shall be in finest flesh. We speak, of course, chiefly of those smaller streams which are a good deal influenced by their immediate banks; for a large river brings more power of character along with it, and of course it is less affected by local causes. But, in streams of moderate dimensions, the presence of minnows in large numbers is always a sign that there are few or no trout to be got there. Minnows shoal only where the banks are shelving and the water shallow; and such places do not suit trout. Worms, too, only come partially into the streams, and those that do come are in great part from wet ground, and trout will not readily take them as bait. Trout never have their finest colour, or are properly filled up in proportion to their length, if there are not overhanging banks of kindly soil, covered with wholesome herbage.

There are perhaps more anecdotes of trout and trout-fishing than there are of salmon; and as a very large trout is a much greater rarity than a very large salmon, it is accounted a greater rarity. If delicacy of food is the object, the small ones, which have the flesh pure white, are preferable to any others; but in this case, as well as in other cases, greatness is, on account of its rarity, probably preferred to goodness. There is one large trout, of which we shall quote the notice from Mr. Yarrell, which seems to have been one of the Anakim of the species.—“A few years since,” says he, “a notice was sent to the Linnean Society of a trout that was caught on the 11th of January, 1822, in a little stream, ten feet wide, branching from the Avon, at the back of Castle Street, Salisbury. On being taken out of the water, its weight was found to be twenty-five pounds. Mrs. Powell, at the bottom of whose garden the fish was first discovered, placed it in a pond, where it fed and lived four months, but had decreased in weight, at the time of its death, to twenty-one pounds and a quarter.” We have heard of very strange notices and noticeable things being sent to learned societies, and, among the rest, of a portion of the blade-bone of a sheep, which had been blackened in the earth, sent and received as “ditto” of the blade of an elk’s horn; but we are far from supposing that there was any hoax in this great Salisburian trout. The close of 1821 was remarkable for its floods—enough to make the monarch of all the trouts mistake a rill for a river; and it is for this reason chiefly that we have noticed the fact of this one. There is no doubt that early winters, or late autumns, according to the climate, which are remarkable for rain-storms and floods, are equally remarkable for the migrations of some of the *Salmonidæ*. This is a curious point in the natural history of fresh-water fishes, and one which has not hitherto received the attention which it seems to be worthy of.

Among the supposed varieties, or even species, of the common trout, there is one which we cannot wholly pass over in silence, and that is the *Gilaroo*, or gizzard trout, which is met with chiefly in Ireland. The stomachs of the *Salmonidæ* are all, in their natural state, membranous, but these are understood to get into places where they swallow crustacea, and more especially mollusca, the crusts and shells of which are too much for a membranous stomach, and so the trout get a sort of gizzard to help them through with this more severe labour. In the specimens of *Gilaroo* trout, examined by Mr. Yarrell with his

usual accuracy, there was found to be no increase of the muscular substance or power of the stomach, though the inner coat of that organ was indurated. It was found to contain in the stomach shelled mollusca, chiefly the *Cyclostomum impervium* of Draparnaud, a small whorled shell, which is very abundant on the shallow bottoms of many lakes. That the stomachs of these trout should undergo the change which has been observed, is one of the most remarkable instances of the dependence of the minor characters of trout upon the nature of their food. It is in Ireland chiefly that the variety of trout, having the hardened coat to the stomach, have been found, chiefly in lakes, or in the outlets between those lakes and the sea.

It seems, too, that there is a great tendency in trout to perpetuate, in the successive generations, the accidental changes which are impressed upon them, even though these are mere definitives. It is said that many of the trout, in some of the rivers of South Wales, have the spine crooked a little in advance of the origin of the tail. In some parts of the Highlands of Scotland they exhibit other deformities; as, for instance, there are some in Lochaber, the black lakes, near Pitmain, in the valley of the Spey, which have the lower jaw of the same length as usual, but the upper one truncated and rounded, so that it is hardly the diameter of that organ in advance of the eye. The cause of this, or the kind of food on which these trout chiefly subsist, are not known; so prone, indeed, are the trout to change their appearance from what appear to us very slight causes, and often in cases where we can see no cause at all, that the natural history of them is an extensive subject, and one to which justice cannot be done in a work intended for the use of the public generally.

Trout are as delicate in their nature as they are susceptible of changes of appearance from natural causes. We have already remarked how they are affected, both in their colours and in the quality of their flesh, by the admixture of the water of peat bogs, which contains only a vegetable admixture; and they are still more affected by anything of a mineral nature. The common trout cannot be brought to bear salt water, or even water which is very perceptibly brackish; but whether the gills or the skin suffer the most in such cases is not known. It is probable that the skin suffers considerably, for all the marine *Salmonidæ* have a different cuticular appearance from the fresh-water ones; and the same may be said generally of most of the fish which range freely through these waters. In farther proof of this, it may be mentioned, that the migrant *Salmonidæ* lose their sea lustre after they have been for some time in the fresh waters. Any mineral impregnation is equally unfavourable to trout. The drainage of a mine is sufficient to destroy those of a considerable stream; a few lumps of quicklime thrown into a pool will soon kill all the trout; and they disappear from the brooks among the corn-fields when these are highly dressed with lime. Nothing is more speedily fatal to them than the water in which flax is macerated, in order that the epidermis may be rotted, and the fibres come easily from each other. In short, there is hardly one product of soil which can get into the waters which is not deleterious to these highly sensitive fishes.

GREY LAKE TROUT (*S. lacustris*). This is a large species, of sequestered habits, residing only in those

upland lakes which are of considerable dimensions, and not rising to the surface, as is done by the trout of rivers and pools. It has of course less inducement, as there are few flies to be found on the surface of a broad lake. Hence, till of comparatively late years, this species was supposed to be peculiar to the lake of Geneva; and even Cuvier, whom no one can accuse of any overweening disposition to change names, called it *Lemnus* after that lake. It is now, however, ascertained to be very far from a rare fish. Indeed, it seems to be one of the most widely distributed of the *Salmonidæ*, and one which is less affected by differences of locality than almost any of the others—we say differences of locality, for there is but little difference of climate or of season in the haunts of this fish. It tenants the great lakes which have deep water, and which may be said to have neither summer nor winter, as the heat affects them but little, and their temperature, even in the bays, never sinks to the freezing point. It has been found in all the great lakes of England, Ireland, and Scotland, which have been carefully examined, and even in the Orkney and the Shetland isles; and, from its appearing so far to the north as these, and also as far south as the Lake of Geneva, there seems to be every reason to conclude that it is very generally distributed among the great lakes of the mountain countries of Europe, and that *lacustris* is the proper specific name.

It feeds on fish much more than upon invertebrated animals, which latter are necessarily but few in the very deep lakes. Accordingly its flesh is of a very inferior quality, dry, tasteless, and of a kind of dull buff-colour. The smaller ones, however, which are found upon the shallows of such of the lakes as have banks running into them are rather better, and the flesh is nearly white. Being generally found in districts where the mass of the people have but few luxuries, it is considered a tolerably good capture. Those resident near the lakes set baited lines for it in the evening, and generally find fish in the morning, as the species is exceedingly active and voracious, and not in any way particular as to what it seizes. Those who have leisure for sporting sometimes angle for it. The young may be caught with the fly, generally on or near the shallows, or, at all events, at no great distance from the bank; but the full-grown ones keep the deeper water, and are rarely or never taken in this way. The mode of fishing for them is from a boat, with a line from the stern or a rod as it happens, and a weight to keep the bait at some depth, to do which it is also necessary that the boat should be rowed slowly. The bait is usually a small trout, and a strong tackle and several hooks are necessary, as the fish cannot be struck in the usual manner, and indeed does not require it. Even though it disentangles itself, it soon bites again, as if it would not be left behind; but the line and rod must be very strong, otherwise the fish will get away. People in crossing some of the lakes often put a grey trout line over the stern, and leave it to chance, and they are not unfrequently successful. We have seen the fish, at least so far as our recollection serves us, taken from some of the Highland lakes long before there was any notice of it as a Highland fish, but we prefer the account given of it in the fifth edition of the *Encyclopædia Britannica*, as that was given after the fish was better known. "When," says the able writer of the article *Angling* in that work, "in per-

fect season and full-grown, it is a very handsome fish, though the head is clumsy, too large and long to be in accordance with our ideas of perfect symmetry in a trout. The colours are, deep purplish-brown on the upper parts, changing into reddish-grey, and thence into fine orange-yellow on the breast and belly. The whole body, when the fish is newly caught, appears as if glazed over with a thin tint of pure lake colour, which fades away as the fish dries, and so rapidly, that the progressive changes of colour are easily perceived by an attentive eye. The gill-covers are marked with large dark spots, and the whole body is covered with markings of different sizes varying in different individuals. In some these markings are few, scattered, and of a large size; and in others they are thickly set and of small dimensions. Each spot is surrounded by a pale ring, which sometimes assumes a reddish hue; and the spots become more distant from each other as they descend below the lateral line. The lower parts of the fish are spotless; the dorsal fin is of the same colour with the upper part of the fish; it is marked with large dark spots; the pectoral, ventral, and anal fins, are of a rich yellowish-green colour, darker toward their extremities; the tail is remarkable for its breadth and consequent power. In adults it is perfectly square, or might even be described as slightly rounded at its extremity; in the young it is slightly forked, and appears to fill up gradually as the fish grows older.

This change of the tail, from being forked in the young, to square, or a tendency to convexity, in the old fish, is common to almost the whole of the *Salmonidæ*; and if the difference of haunt and habit attending it in its various changes were fully investigated, it would perhaps throw some light upon the use of the differences of outline in fins, a subject of which we at present hardly know any thing. The grey trout grow to a very large size, specimens being met with nearly or altogether three feet in length, and weighing twenty pounds or upwards; but these are caught but rarely, and that always with bait in the deep water. It is possible that the fishing of them might be carried on to a considerable extent by many float-lines similar to those used for white fish in the sea, only the impossibility of giving much motion to the baits upon such lines might be an objection to their use. The great objection, however, is the want of a market, and the unmarketable quality of the fish. It is proved by very general observation, that the people of remote places where fish are abundant and of good quality, will hardly take the trouble of capturing enough for their own use, unless they have the prospect of a profit from sale; and this, by the way, seems to be one of the chief reasons why so little was known of the fishes, even of our own islands, before the commencement of what may pre-eminently be called "The age of Natural History."

GRAYLING (*Thymallus vulgaris*). This species has the general characters of the family certainly; but they are much more modified than in any of those that have been hitherto noticed in this article. The characters are: the head and body elongated, and the back more curved in the outline than the belly, and not the two of similar curvature as they are in the genus *Salmo*, properly so called. The scales are marked by bands running the whole length; the scales are in longitudinal rows, and the lateral line can hardly be traced otherwise than by the straight

rows of scales; the fins are the same in number and situation as in the true salmon, but they differ in form and development; the dorsal is very broad, consisting of as many as twenty rays; the tail has the same number, but it is narrow and feeble, and much more forked at the end than in the salmon and trout, when they are of the same size; the mouth is also much less in the opening than in the salmon, and the teeth are comparatively smaller than in any of the trout. The fish is indeed very inferior to the proper members of the *Salmonidæ* in point of teeth, for it wants the two rows on the tongue, and those on the vomer are only one or two, very small, and confined to the fore part. The size is less than that of at least some specimens of all the species of the trout; for five or six pounds is an extraordinary weight for the grayling. The usual length is about ten inches or a foot.

All these characters show that the grayling is a feeble fish as compared with the trout, both as respects its powers of motion and its feeding; and it seems to be as delicate as it is feeble. It is not in respect of climate, however, that this fish is delicate, for it is found in the very coldest parts of Europe; and is perhaps more abundant in the rivers which discharge their waters into the Baltic than it is any where else; but it seems particular as to the quality of the water and the ground in which that water is situated. Mr. Yarrell says, "However fastidious in the quality of the water, or the choice of situation in the stream, the grayling is known to be, experiment has proved that this fish will live in ponds that have been newly made out of hard soil, or such as have been very recently and carefully cleansed out; but in those situations the grayling does not breed, and they will not continue to live in old muddy ponds."

This statement,—and all that the author of it advances as his own may be implicitly relied on,—throws a good deal of light upon the character of the fish in relation to its haunts, and shows that if the country is not one of a very peculiar character, the grayling can be nothing else than a trial fish, one for which we might seek in vain in mountain streams tinged with moss; in rivers wending slowly through rich countries, and depositing mud, or in ponds or stagnant waters of any description. Clear running water and a hard bottom are obviously the proper situation for the fish; and there are instances in which these circumstances confine it to a particular part of a river, without being found either higher up or lower down. This is the case in the river Dee in North Wales. There are plenty of trout in all parts of the Dee, from the lake of Bala to the commencement of brackish water in its estuary; but the grayling is confined to the part of the river between the lake and the town of Corwen; or, at all events, it is not found so far down the river as the vale of Llangollen, though there is excellent trout fishing.

The fact of its being confined to an intermediate portion of the Dee, which has very clear water and a hard rocky bottom without any deposit of mud, might have sufficed completely to prevent the formation of the opinion that the grayling is a migratory species, which has been stated by Donovan, and also by some of the continental writers; for all the *Salmonidæ* that visit the sea, are sure to be found in the lower parts of the rivers, whether they are in the upper parts or not; and there is really nothing in the Dee to prevent either the ascent or the descent of a

fish, for though there are currents and rapids, there are no falls of any consequence.

The whole structure, economy, and nature of the fish are against the fact of its migration, and may make us very reasonably doubt the allegation of Black, that they descend to the Baltic in autumn. From the character of its fins, the grayling must be but a poor swimmer, even within the range where it is found; and Sir H. Davy ascertained that it cannot live even in brackish water. Besides, the grayling spawns in the end of spring and the beginning of summer, and is in the very best condition in autumn, when all the typical *Salmonidæ* are out of season. We must therefore regard the grayling as wholly a river fish, peculiar in its localities, and confined to them. England, and perhaps Orkney, are the only parts of Britain in which it is found, though in some of the rivers it is very plentiful; but we never heard of its being found along the whole range of any river from its source to the sea; it is always in the clear water on the hard bottom. Its food is understood to consist, in great part, of insects and their larvæ. Its flesh is highly prized, though some part of the estimation in which it is held, may be owing to the fact of its not being to be had, except at particular places; and some more may be owing to its particular fragrance, which slightly resembles that of thyme, and is the reason of the name *Thymallus* being applied. The grayling is taken chiefly by angling with the flies which are on the water, or baits formed of the larvæ which are deposited there; besides these, however, it eats the small-shelled mollusca; but, we believe it rarely preys on any kind of fish, unless mere fry, and probably not much upon these. The grayling is a distinct genus,

PARR (*S. salmulus*). This species has many more of the characters of the salmon and trouts than the grayling, and were it not that the body fins are much more developed, indicating a different mode of action in the water, it might pass for a little salmon, which is the reason of its having the specific name *Salmulus*. As long, indeed, as colour was considered to rank high among the specific distinctions of animals, this was regarded as the young of one or other of the migratory species, chiefly the salmon trout; nor have there been wanting some who have made the distinction of salmon parr and trout parr. Laws have been enacted too, or, at all events, measures taken to prevent the capture of this little fish, lest the number of salmon should have been thereby diminished. But if any one had attempted to identify a salmon, by asserting that he knew it from its being a parr, the party so doing would have been in the same predicament as the Highland witness, who swore to the identity of the gun, because he had "kenn'd her ay sin' she was a wee pistol;" and any one who had examined a parr side by side with a salmon or trout of the same size, would have seen that the one was an animal with all its organs fully developed, and the other was not. The head of the salmon smault is "infantine," if the expression may be allowed; the fins are all small and feeble, and the tail is narrow and much forked. In the parr, on the other hand, all the lateral fins are better developed in proportion than in the full-grown salmon, and perhaps the same may be said of the caudal fin, though that remains a little forked, and indicates that the parr is to act in the same parts of the waters as the young salmon, only not in the same manner. This is proved by the

greater power of the fins; for we never find power given by nature, unless the owner, in the average economy of its species, has occasion for it.

The reason of all this perplexity about the parr was, that they looked only at the colour of the fish, and not at the peculiarities of its organs. "There's saumons in them both," was one of Fluellin's proofs of the identity of the rivers of Monmouth and Macedonia; and "there's spots on them both," was the ground on which it was concluded that the parr and the fry were "both saumons." Mr. Yarrell has the merit of settling the point about the spots, by showing that they are upon the young of all the true salmon and trout, that they can be traced on the skin after they have disappeared from the scales; and it may be added, that the dusky blotches which are on the sides of full-grown salmon, are remains of the general marking on the young. We believe that these dusky markings on the sides are not found even in the young of the grayling, the guinad, and the other species which depart more from the true salmon character in other respects. The family, however, want some further observation as to these and several of their other characters.

In addition to this, it has been proved again and again, that there are parr in places where neither salmon or trout is to be found, either young or adult, and *vice versâ*; and also, that salmon have been almost exterminated from rivers, without the slightest diminution of the numbers of the parr in them.

Still it is understood that the parr (small as it is, for eight inches is reckoned a very large one), is migratory, spawning in winter or in early spring, thereafter descending the rivers, and returning upwards in the summer. As a British fish it is very common in many of the rivers in the southern and warmer parts; but the number fall off as we proceed northwards, and they are not found in the very cold and high-situated streams of the mountains. The following is the description of the colour as given by Dr. Heysham: "Head green and ash-colour; gill-covers tinged with a variable green and purple, and marked with a round dark-coloured spot; in some specimens there are two of these spots on the gill-cover; back and sides, down the lateral line, dusky marked with numerous dark-coloured spots; belly white; along the lateral line there are from sixteen to thirty bright vermilion spots; the sides are marked with nine or ten anal bars of a dusky-bluish colour; dorsal fin with a few dusky points; colour of lower fins inclining to yellow."

The parr, as we might suppose from the great development of its fins, is a most energetic little fish, dabbling about in the water with great celerity, and small as it is, it is exceedingly voracious. Insects and larvæ, and probably small crustacea and mollusca, appear to be its chief food; and, as is the case with most fishes that feed upon this kind of aliment, its flesh is very good. As is the case with many species, it has different names in different localities; and as the parr have in some instances been considered salmon fry, salmon fry have in other instances been mistaken for parr. They are, however, easily distinguished by the times that they are in the rivers, as well as by the other circumstances that we have mentioned. They are found in the rivers after the salmon fry have all descended; and when the salmon return, even in the first year they are in the state of grilse, they are far larger than parr. The last mistake

about these fish which we shall mention, is the allegation that they are hybrids, and as such all females. Neither part of this is true; they follow the general law of the family in their reproduction; and though they were hybrids, all hybrids are not females.

CHARR, OR NORTHERN CHARR (*S. umbla*). This is a lake fish, still preserving the salmon and trout characters in some respects, but differing considerably from them in others. These are decidedly lake fish, never descending to the sea, even if the outlet of the lake is short, and not going into the streams which feed the lake, unless these are clear with rocky bottoms, and then only for the purpose of spawning. They occur in the greater part, if not the whole, of the lakes of Westmoreland and Cumberland, in many of those of Scotland and of Ireland, in the lake of Geneva, and in various other lakes of continental Europe. It is, however, always in alpine lakes with rocky bottoms, and with the water clear, that they are found. They do not appear in any of the large pools of the low and fertile districts, and even those of the Welsh lakes are different from the English ones. They are not, generally speaking, very large fishes. They are met with as long as a foot and a half, or from that to two feet; but generally they are not found above half these lengths.

They are subject to considerable differences of colour and of lustre, the causes of which are not very well known, and this has caused them to be called by a variety of names, such as case-charr, gilt-charr, red-charr, and silver-charr; but there do not appear to be very real specific distinctions between those that are so named.

Charr are retiring fishes, and inhabit the deeper parts of those lakes in which they are found; and they feed chiefly during the night, so that the catching of them is much less certain than that of many other fishes of the same lakes in which they are found. Fly-fishing, expressly for the capture of charr upon the lakes, would be an employment of far more labour than reward; but one is occasionally taken by those who fish for trout, which is a proof that they do occasionally catch flies at the surface. They are far more certainly obtained, however, by a minnow bait, which must have a heavy sinker at a little distance on the line to carry it to a considerable depth; and even then the fishing is much more one of curiosity than of profit. In those places of the British islands where they are most plentiful, they are in the best condition in the early part of the summer. Soon after this, the operation of spawning commences; and if the streams which fall into the lake have rocky bottoms, they ascend them in considerable numbers, but never to any great distance; and if they find, after they have entered the stream, that it is not suitable for their purpose, they return, and seek for another better adapted for their purpose.

In form and in the relative proportions of the head and body, the charr are nearly the same as the more typical *Salmonidæ*, but the dorsal and caudal fins are rather further forward. The head is one-fifth of the total length, and the depth of the body at the thickest part a little more. The pectoral fins are small; the tail is deeply forked; and all the fins are of moderate dimensions, indicating that the fish is not of a very discursive character. The eye is large, the teeth small, and only a few on the anterior part of the vomer. The top of the head and all the upper part are, when the fish is in high condition, of a rich

brown. This becomes lighter on the sides, and passes into rich orange on the under part, which is also the colour of the pectoral, ventral, and anal fins, excepting that the first ray of the ventrals and the anals is white. The sides are marked with numerous spots of a red colour both above and below the lateral line. That line is nearly straight, but rises at the posterior extremity, so as to meet the upper corner of the gill-cover. The gill-covers are dull orange with a greenish and brownish tinge; the irides are bright orange; the dorsal and caudal fins brown, with a slight gloss of purple. The scales are very small and ranged in oblique rows across the depth of the body. When out of season, the colours fade or alter so much that some have described it as a different fish. The brown on the upper part has then a dull purplish hue, gradually becoming duller on the sides, which are silvery, and the belly is very pale orange. The most remarkable change, however, is that of the lateral spots, which are of a fine red when the fish is in good condition, but which fade to white when it is not. The gill-covers and the irides also change to a silvery hue at this time; the dorsal fin is dull brown, the caudal fin purple brown, and the other fins brownish red. In fact, the changes of colour are so great that one can hardly wonder that the fish in the two states has been very generally described as two distinct species; and as, in the time of its "bloom," or finest colouring, there are considerable differences that has occasioned the description of it as three species. In its brighter colours it is *S. salacinus* of authors, and when the colours fade it is *S. albinus*. Dr. Fleming, in his account of British animals, has enumerated it as both, calling it by the same local name as the Welsh charr when in its gayest colours, and as such referring to the mountain lakes of Wales and Scotland as its habitat; and as the case-charr when out of condition, referring it then to Winandermere, as if it were found in that lake only. He has also been misled respecting the number of rays in the fins in both, making twenty four in the caudal, where there are only nineteen; eleven in the dorsal where there are thirteen; sixteen in the pectoral when the colours fade, and thirteen when they are at the finest, while there are twelve in both states; and ten in the anal in the one state and eleven in the other, when there are eleven in both. These blunders are, however, excusable, as the charr is a sort of *Proteus* among fishes, and has the branchiostegial rays sometimes in different numbers on the two sides of the same specimen; and therefore we can hardly expect that the number of rays in the fins shall be constant.

WELSH CHARR (*S. salacinus*). This is the species which Fleming describes as the red-bellied charr. It is in shape a much more clumsy fish than the charr; but, from the development of its fins, it appears to be more powerful in the water. In Wales it is a very local fish, being found only in one or two of the lakes; and the fact of its being met with in the Highlands of Scotland wants confirmation. It is rather a small fish, not occurring of a greater length than about seven inches, but it is esteemed a very delicate one for the table, partly, no doubt, on account of its rareness. This circumstance may both explain and excuse the mistakes that appear to have been made concerning it.

It has some resemblance in the form of the body, and the development of the fins, to the parr when that is of mature age, and one can trace the same

blotches across the lateral line as are in the parr. But the teeth are very different, there being very few on the vomer, still the other teeth are considerably larger than those of the charr of the north of England. The habitats mentioned for the Welsh charr are, the small but deep lakes of Llanberris and Cawellyn on the two sides of Snowdon, and a few other places in North Wales; but it is said to have been destroyed out of the lake of Llanberris by the discharge of the water from a copper mine into that reservoir, which is very likely, as none of the *Salmonidæ* could live in water impregnated with the discharge from such a mine.

The length of the head and the depth of the body in the Welsh charr are each one-fourth of the whole length of the fish, whereas in the other charr they are only about a fifth. The dorsal and ventral fins are also farther back; and all the fins, as already noticed, are much more produced. There are fewer rays in the dorsal, pectoral, and anal fins; and although the body is shorter in proportion to its depth than almost any other of the *Salmonidæ* have it, the number of vertebrae is greater, being sixty-two, while it is fifty-nine in the northern charr and sixty in the salmon. The whole upper part of the fish is greenish black, or very dark olive; the sides are olive on the upper part, passing into golden yellow below the lateral line, and again into reddish orange on the belly. The sides above the lateral line are marked with white spots, and upon and below it with red. The irides are hazel, the sides of the head and the gill-covers pale olive, the pectoral, dorsal, and caudal fins brown, and the remaining fins the same colour as the belly. From the brightness of the colours upon this fish, it is probable that they fade when it is out of season, as is generally the case in very brilliantly-tinted fishes. We have heard a red-bellied trout mentioned in some parts of the Highlands of Scotland; but, as we never saw it, we cannot tell whether it was this species or not. Those whom we heard mention it were not likely to pay attention to the most remarkable character—the numerous teeth on the vomer in the trout; and as the grey trout of the alpine lakes has the belly reddish orange in some of the specimens, it may have been the one to which the name of red-belly was applied.

GWYNIAD (*Conegonus*). This fish belongs to another genus, of which there are various species or at least varieties on the continent of Europe, but they are not very clearly made out. The name *groyniad* means white, which is not undescriptive of the fish, though it gets different names in other parts of Britain. In its general form and in the arrangement of its scales, it resembles the grayling more than any of the salmon or trout, and it may be considered as a sort of intermediate link between the typical *Salmonidæ* and the herring family, having a good deal of the character of the latter.

This fish is found in some of the Welsh lakes, in those of Cumberland, where it is especially numerous, and, as the authorities say, in some parts of Scotland, though this is a little doubtful. In Ireland there is a fish something resembling it, but perhaps not the same; and there are others in various parts of continental Europe, and probably also in the lakes of at least some parts of North America. Wherever they occur, they are sometimes called fresh-water herrings; and though they have not the details of the herring character, they have something of the shape. It is a

fish which can be kept only a very short time after it is caught, and even then it is not of the very first quality; but the country people sometimes salt it as a store against the time when fresh fish cannot be obtained.

The spawning time is winter, or very late in the autumn; and the fish do not leave the lakes in which they reside, at least to any great distance, for the performing of this operation. The length of the groyniad when full-grown is from ten inches to a foot; the head occupies about one-fifth of the total length; and the depth of the body at the thickest part is rather more than the length of the head. The dorsal fin rises midway between the nose and the base of the tail, and the ventral fins are immediately under the middle of the dorsal. The tail is considerably forked. The snout is pointed, and the head of a triangular shape when viewed laterally. Both the upper and the under outlines have considerable curvature, but the upper one has the greatest. The pupils of the eyes are dark blue, and the irides silvery. The upper part of the body and the tips of the fins are dusky blue; this colour becomes paler on the sides; and the under parts, and also the gill-covers and sides of the head, are silvery. The usual number of rays in the fins are: thirteen in the dorsal, seventeen in the pectoral, eleven in the ventral, sixteen in the anal, and nineteen in the caudal. The variety found in Ireland, chiefly in Lough Neagh we believe, has the muzzle blunter, the dorsal fin farther forward, the anal fin with fewer rays, and all the fins generally of smaller size.

VENDACE (*Coregonus Willoughbi*). This fish is of the same genus as the groyniad, and resembles it in a good many respects, but there are specific differences; and the vendace, as a British fish, is still more limited and local in its distribution. It is found only in the waters of Lochmaben and some other small lakes in that part of Dumfries-shire, into which tradition says it was imported by Mary Queen of Scots; and as there is some romance about the fish, and its dwelling is in a romantic and somewhat romancing part of the country, the probability is that it will not soon be given up. There is rather a curious coincidence between one of the cognomens of the lake of the vendace and one of those which have been the most celebrated for Welch charr; "the Money Loch" is one of the names of Lochmaben, for Burns says of the town—

Margery o' the Money Loch,
Where lang she did abide;

and Cas-y-gedawl, the name of one of the lakes by the side of Snowdon, has a similar meaning. The vendace is not confined to the Castle Loch, or Loch of Lochmaben by way of eminence, but occurs in the neighbouring ones, though in no other part of Britain. There are species somewhat analogous in some of the lakes on the continent, but they have not been examined with such care as to enable one to decide whether any of them is precisely the same with this one; and indeed a fish of so changeable a family, confined to a narrow locality, may be supposed, if originally an importation, to have taken a character from its new abode. Sir William Jardine, to whom we owe an interesting account of it, the only good one that has been given from actual observation, conjectures that it may have been introduced by the monks rather than by Mary. This we think very

likely, for the holy fathers were fond of every thing that promoted good cheer. It is said that they introduced the grayling into England; and, whether that was the case or not, we know that they were the first introducers of many of our best sorts of fruit trees, and of an improved breed of cattle.

Vendace is but a small fish, the female being usually under nine inches in length, and the male not exceeding seven. The following is an extract from Sir W. Jardine's account of it:—"In general habits, the vendace nearly resemble the groyniad, and indeed most of the allied species of the genus. They swim in large shoals, and during the warm and clear weather retire to the depth of the lakes, apparently sensible of the increased temperature. They are only taken (taken only) with nets, a proper bait not being yet discovered; and the fact that little excrement is found in their intestines has given rise to another tradition, that they are able to subsist without food. They are most successfully taken during a dull day and sharp breeze, approaching (as they then approach) near to the edges of the loch, and swimming in a direction contrary to the wind. They spawn about the commencement of November, and at this time congregate in large shoals, frequently rising to the surface of the water in the manner of the common herring, and making a similar noise by their rise and fall to and from (from and to?) the surface. The sound may be distinctly heard, and the direction of the shoal perceived, during a calm and clear evening. They are very productive. The lochs abound with pike, of which they are a favourite food; but their quantity seems in no degree diminished, notwithstanding that vast numbers must be destroyed. They are considered a great delicacy, resembling the smelt a good deal in flavour; and, though certainly very palatable, the relish may be somewhat heightened by the difficulty of always procuring a supply. During the summer, fishing parties are frequent, introducing some stranger friend to this Lochmaben white-bait; and a club, consisting of between twenty and thirty of the neighbouring gentry, possessing a private net, &c., meet annually, in July, to enjoy the sport of fishing, and feasting upon the luxury."

The opinion which Sir William mentions, not his own of course, for he knows better, but the current opinion of the place, respecting the abstinence of these fishes, which is often selected with regard to salmon and to others of this family, as well as of the somewhat allied family of the herrings, is in direct opposition both to the analogy and the fact. The analogy is that, wherever there is much energy of action in an animal, there must be a corresponding supply of food to support the waste occasioned by that action; and the fact is, that all the family are ravenous feeders; that there should not be much of the remains of the food found in the intestinal canal is more a proof of the digestibility of the food and the power of digestion than any thing else. Mr. Yarrell found a copious supply of food in the stomach, but so acted upon that a microscope was necessary in order to ascertain its nature; and then it was found to consist of various small *entomostracous* crustacea, with the remains of small worms, beetles and flies, showing that these fishes are not at least confined to one species of food. The crustacea are swimmers, and probably so are the beetles alluded to; and therefore the vendace may, like most of the lacustrine species of the genus, find their food while they swim in the water, without

often rising to the surface. The food is in very minute portions, but it is of the kind which is understood to be most nourishing for fishes, and productive of the finest flavour of their flesh.

SMELT (*Osmerus epirianus*). This is a small species, but it is one which is held in high estimation. It is found in the estuaries, generally about the top of the brackish water, or perhaps a little higher up, but not in the offings or very much in the fresh water, though it spends fully half the year there. They ascend in autumn, and descend again about the beginning of summer, the spawning time being about March, though of course varying with the place and the season. They prefer the quiet waters where the bottoms are rich, and generally congregate in a small space, moving a little with the tide. Their food consists chiefly of the smaller crustacea; but they can be taken with fly, though the net is used in their capture, as it is in that of most of the shoaling fishes. The sea is not absolutely necessary, for they have been bred in fresh water ponds, and have succeeded well. They are generally about seven inches in length, but one now and then occurs of ten inches or a little more. The form is long and slender, the tail much forked, and the anal fin continued with short rays nearly to the base of the tail. All the upper parts of the body are pale greenish ash, and the under parts of a silvery white. The fins yellowish, with black dots on the extremity of the caudal. As is the case with many others of the family, they avoid impure water; hence they are found in the estuaries of particular rivers only, and if a river, from any cause, becomes very foul, they desert it not to return. They seldom go far above the brackish water, and rarely out of the tideway, which seems to have considerable influence on their food.

Such is an outline of the leading members of the salmon family which are to be found in Britain. A few more have been mentioned, and there are many more in the northern parts of both continents; but we have already exceeded our limits, and must take leave of them, with simply remarking, that in the pleasant season of the year they are among the greatest attractions of the waters.

SALPIGLOSSIS (Ruiz and Pavon). A genus of annuals and perennials from Chile. They have handsome didynamous flowers, and belong to *Solanææ*. These plants are treated as tender annuals, that is, sown in pots in the greenhouse or frame, and afterwards placed in the flower-border to bloom.

SALSAPY is the *Tragopogon porrifolium* of Linnæus, a British plant introduced into the kitchen garden, and cultivated for its fusiiform roots, which are used as a table vegetable.

SALSOLA (Linnæus). A genus of herbs, chiefly annuals, found wild in many different parts of Europe. They belong to *Chenopodææ*, and in Britain are called saltwort, because the species grow on the sea-shore. In Spain the *Salsola kali* is extensively cultivated for the manufacture of barilla, as sea-weeds are for kelp.

SALTICUS (Latreille; ATTUS, Walckenaers). A numerous genus of spiders, distinguished by their elongated form, the comparative shortness and strength of the legs; the eight eyes arranged in a large quadrangle opened behind, the two central ones in the front row being large. These are wandering spiders which do not spin webs, and are to be observed on walls, palings, &c., in hot and fine weather; they are

extremely active, and exhibit a very considerable degree of intuitive caution in the capture of their prey, which they seize by a sudden leap, "and therefore," observes Swammerdam, "nature has provided them as well as other spiders with eight eyes." The proceedings of one of these spiders is thus interestingly recorded by Evelyn, "which espying a fly at three or four yards distance upon the balcony where I stood, would not make directly to her, but crawl under the rail, till being arrived to the antipodes it would steal up, seldom missing its aim; but if it chanced to want any thing of being perfectly opposite, would at first peep, immediately slide down again, till taking better notice, it would come the next time exactly upon the fly's back; but if this happened not to be within a competent leap, then would this insect move so softly, as the very shadow of the gnomon seemed not to be more imperceptible, unless the fly moved, and then would the spider move also in the same proportion, keeping that just time with her motion as if the same soul had animated both these little bodies, and whether it were forwards, backwards, or to either side, without at all turning her body, like a well-managed horse; but if the capricious fly took wing and pitched upon another place behind our huntress, then would the spider whirl its body so nimbly about as nothing could be imagined more swift, by which means she always kept the head toward her prey, though, to appearance, as immovable as if it had been a nail driven into the wood, till by that indiscernible progress (being arrived within the sphere of her reach), she made a fatal leap, swift as lightning upon the fly, catching him in the pole, where she never quitted hold till her belly was full, and then carried the remainder home." There are a considerable number of species belonging to this genus, the type being the *Salpicus fornicarius* of Latreille, a common British species.

SALVIA (Linnæus). A very extensive genus of herbs and undershrubs, found in all parts of the world. The flowers are, by abortion, diandrous, but they manifestly belong to *Labiataæ*. There are above one hundred and twenty species of sage. One is a well-known culinary herb, and some are so highly ornamental, that they are placed in the first rank of greenhouse plants. They are all easily propagated by cuttings.

SAMBUCUS (Linnæus). A well-known genus of herbaceous, and chiefly shrubby plants, natives of Europe and North America. They belong to the third order of the class *Pentandria*, and to the natural order *Caprifoliæ*. The elder is seen on every spot of waste ground, and yet it is cultivated in some places for its flowers and fruit. A cosmetic and ointment are made of the former, and a kind of wine from the latter.

SAMOLUS (Linnæus). A genus of small herbs, one of which is a native of Britain, and called brooklime. The flowers are pentandrous, and the genus belongs to *Primulacææ*. If brought into the garden, they must be placed in a moist soil.

SAMPHIRE is the *Critinum maritimum* of Linnæus, a British rock plant, so much sought after and prized as an ingredient in salads, and as a pickle.

SAMYDEÆ. A small natural order, containing only two genera, viz., *Samyda* and *Cascaria*, and of these there are fourteen species. They are tropical shrubs or small trees, with entire stipulate alternate leaves, covered with peltate dots and axillary flowers

of little show. Some of the species of *Samyda* are pretty, but very rare. The calyx is of from three to seven sepals, coherent by their claws; the corolla is absent, or reduced to a thin torus that lines the bottom of the calyx; the stamens are definite, two to four times as many as the sepals, and exserted from the calyx; the filaments are monodelphous and subulate, either all antheriferous, or alternately fertile and barren; the germen is free or superior, one-celled, and many ovules; the style is filiform, and the stigma lobed; the bark and leaves of the *Samyda* are said to be slightly astringent; and the leaves of *Cascaria ulnifolia*, when boiled, are applied in Brazil to wounds, and are there reputed an antidote to the bites of poisonous serpents. Some of both genera are in our stoves, grown in light soil, and increased by cuttings.

SANDERLING (*Calidris*). A genus of birds belonging to the long-billed family of the stilt birds, resembling the genus *Tringa* in most respects, excepting that it has no hind toe like the members of that genus. The characters are: the bill of mean length, straight, soft, and rather flexible, compressed at the base, depressed at the point, and flattened for the greater part of its intermediate length; the nasal grooves continued almost to the tip; the nostrils placed longitudinally in the sides of the bill; the feet slender, with only three toes, all directed to the front, and free their whole length. There is only one species of the genus, but it is found more generally distributed than birds of other genera containing many species, being common in all the northern parts of Asia, Europe, and America—in none of which places there seems to be the slightest specific difference, though there are climatal distinctions between very many other genera as natives of the eastern continent and of America.

Abundant as the sanderling is, the history of it is involved in considerable obscurity. It is most frequently seen along the shores in the autumn and winter, for it flocks at that season. In summer, however, there are a few that linger till the season is considerably advanced, and then may breed in the country, though where does not appear to be known. In the arctic countries they breed in great numbers, making their nest-holes in the sand, and depositing five or six eggs, upon which the female sits very closely.

The plumage varies considerably with the season, the age, and the sex of the birds; but the bill, the feet, and the irides, are at all times black. The summer colours are brownish-ash on the upper part and reddish-brown on the under; but the under part begins to get mottled with white in the autumn, and becomes entirely white in the winter, the white extending to the forehead, and also to a streak across the eye. Sanderlings, when they are with us, are always on the margins of the sea, or on the rivers at no very great distance inland. They live chiefly upon the small crustacea and mollusca, which they pick up between the wet and the dry. Thus they follow the tide on the sandy beaches, and communicate a lively interest to them at the time when the land is most desolate. They are light-looking birds, and also birds of powerful wing for their size. The length is about eight inches, and the extent of the wings about twice as much. When alarmed they rise in a flock, and escape by a wheeling flight.

SANDORICUM (Cavenille). $\frac{z}{2}$ An East Indian

timber tree, belonging to *Meliaceæ*, and called sandal-tree. It grows freely in a mixture of sandy loam and heath mould, and is increased by cuttings made of the half-ripened wood.

SANDPIPER (*Totanus*). An interesting genus of stilt birds, of the long-billed family, and forming a link in that numerous chain of birds which have their general habitat, as it were, between the land and the water. They are all, it is true, land birds; for, though some of them can enter the water, none of them have the feet webbed for swimming. Their pasture extends from the solid bank, where water never remains to stagnate, to the sea within low-water mark, which is never dry. This pasture of theirs is, in general, covered with sand or gravel, though sometimes with sludge, and at other times with vegetation, passing gradually from the land character to the aquatic. In some situations it is miles in breadth, and in others it is only a line upon the perpendicular face of the cliffs, on which the water rises and falls, and where there is of course no footing for a bird.

One would be apt, at first thought of the matter, to suppose that this must be the most barren portion of the whole surface of the earth; but, so far is this from being the case, that it is really very fertile, and its productiveness continues the whole year round with much less interruption than upon the land. From its composition and surface, the sun exerts a great deal of influence upon it, so that, in almost every part of the world, it is the line of greatest average annual heat. Hence it produces an immense number of small living creatures, and these supply food for great numbers of birds, among which the sandpipers hold not an inconspicuous place.

The bill of the sandpipers is flexible in the basal half of its length, but it becomes firm toward the tip, with sharp tonia, and a nail on the extremity of the upper mandible which covers over that of the under one. This is sufficient for enabling the bird to break the crusts of those little animals upon which it feeds, while the flexible portion takes off the jar which would otherwise be given to the head when the bird searches among the sand and shingle. The legs are long, and have a garter or portion of the tibiae, above the tarsal joint, bare of feathers; their wings are long and pointed, the first quill being the longest, and thus they are well adapted for flying in circles, as they beat over the surface to find the places where food is to be had. Their eggs are four, placed in quatrefoil, and generally on the bare surface, without any formal nest. These eggs are large for the size of the birds, generally of the colour of sand or of small gravel, and with the ends very different in thickness. They are noisy birds, and utter shrill and wailing cries, but these are rather pleasant, as they break the monotony of the expiring waves, sighing on the sand, or murmuring among the pebbles. We shall very briefly notice the British species.

RED-SHANK SANDPIPER (*T. Calidris*). As a British bird, this species is resident within the country, only it shifts its ground with the seasons. It is on the shores from the middle of autumn to the end of spring, and the rest of the year it is on its breeding-grounds. These are the borders of the marshes in the south part of the country, and those of the inland and upland bays in the north. The nest is in a tuft, very rude in structure, and the eggs are four in number, pale olive on the ground colour, and marked

with brown blotches, especially toward the thick ends. They do not go quite so far inland as the lapwing, nor do they build so much on the open moors, so that they are not so often seen or heard as these amusing birds; but when their nests are approached, they set up a wailing, and wheel about in the air, hinting to the intruder that he is treading forbidden ground.

When on the shores, they do not assemble in flocks, like many of the birds that winter there; they are scattered about, and thus they do not appear to be so numerous as they really are. Even then, however, they are noisy, and their whistle may be heard amid the roarings of the surges as these break on the shore. At this season their colour is ash-brown, with dusky streaks on the back, and the breast greenish-white, with faint lines of brown.

The length, when full grown, is eleven inches, and the stretch of the wings nearly twice as much. The feet and the basal half of the bill are orange-red, the point of the bill dusky, and the whole bill is about two inches in length; the tarsi are long, and there are very slight webs between the first and second toes at their bases; the irides are hazel, and the naked space round the eye greyish white. In summer the back, and upper parts generally, are dusky, spotted with grey, with the exception of the wing-coverts, which are ash, spotted with white and brown; the quills are dusky, with white tips to the secondaries; the rump white, spotted and barred with dusky; the tail with alternate bars of white and black; the breast white, with oblong dusky spots, and the belly pure white. The young of the year have the upper part brownish, and the breast ash-coloured, with a few brown lines. They have sometimes been regarded as a distinct species.

COMMON SANDPIPER (*T. hypoleucos*). This species is rather a small bird, being only between two and three ounces in weight, and little more than seven inches in length; but it is a very active little bird. The colours of the upper part are ash, variously mottled with brown; the under part is white, with brownish lines on the breast; the feet are admirably fitted for running, an operation which the bird performs very swiftly. It often runs into the shallows of the water, and it can swim a little, for its feet are webbed nearly to the first joint of the toes, and the feathers on the under parts of its body are close and waterproof like those on the swimming birds. This species is very abundant in all parts of the British islands, which suit its habits, and passes into several of the western isles; but we believe it is not met with in the extreme north. In the severity of winter the greater part migrate, and leave our shores to birds less fitted for long flight. This one has very great powers in that way. Its wings are rather more than twice the length of the body, and they are firmly made. The tail is also an efficient instrument. It can be spread out like a fan, and the bird uses it both in picking up its food and in its ascents and descents. They disperse themselves widely over the wilds in the summer, frequenting the margins of the streams, and making their rude nests under the banks, or simply among the sand and pebbles, if there is no bank at hand. The nests are not very often seen; for the bird, when surprised, gets away so fast, and with so many doublings, that one cannot easily mark the place where it rises. Their cries are shrill and often repeated, and, as they are heard

in bleak and lonely places, they are pleasing. The eggs are four, of a whitish flesh colour, mottled with dark reddish brown. They are not found in the rich parts of the country; and there do not seem to be half so many of them any where as there really are, for they live very dispersedly.

GREEN SANDPIPER (*T. chloropus*). This is a larger and heavier bird than the common sandpiper, being more than nine inches in length, and weighing between three and four ounces. It is a resident bird, wintering as well as summering in Britain; and it is an inland one, building near the wild lakes and marshes, and frequenting their margins in the winter, unless when the weather is very severe, and then it betakes itself to the sea-coast. The bill and feet have a dull greenish tinge, only the head or distal part of the bill is dusky, as it generally is in the genus. The bill is very slender, but firm in its terminal part; the feet have webs between the outer and middle toes only. In summer the back is brown, with green glosses and some small white spots. The lower parts are white. The upper part is paler in the winter, and has not the glosses. The nest is near the waters, composed of a little withered grass if on the soil, but merely a little hollow if on the sand. This is also a very pretty tenant of the wilds, but, like the rest, it is not often seen.

WOOD SANDPIPER (*T. glariola*). This is rare, and by some supposed to be a winter migrant from the northern parts of Europe, where it is abundant; but the time of its appearance in the south of the country is rather against this. It is smaller than the green one. The upper part dusky and glossed with purple, and the under parts white.

There are many other species, some of them British, and among the rest the greenshank; but there is nothing very particular in their habits, which are pretty uniform in all the genus.

SANGUINARIA (Linnaeus). The *S. Canadensis* is the puccoon or bloodwort of North America; a polyandrous flowering, tuberous-rooted perennial, belonging to the natural order *Papaveracea*. This dwarf-growing plant thrives in any light soil, and is increased by seed or divisions of the root.

SANGUISORBA (Linnaeus). A genus of herbaceous perennials, mostly European. The flowers tetrandrous, and the genus belongs to *Rosaceæ*. The *S. officinalis* is a pasture plant in English farming, and known by the name of burnet. Although a portion of the seeds be frequently employed in laying down permanent pastures, cattle do not seem to be fond of it, as it is the last to be eaten.

SANICULA (Linnaeus). A genus of British and North American herbaceous perennials, belonging to *Umbelliferae*. The species are uncultivated, and only noticed by the botanist.

SANTALUM (Linnaeus). A genus of tropical trees and shrubs, belonging to the natural order to which they give a title, viz.

SANTALACEÆ. A natural order, containing seven genera, and above twenty species. They are chiefly natives of South Africa, New Holland, and India, and collectively considered, are trees, shrubs, or herbs, with round or irregularly angled branches, alternate, nearly opposite leaves, stipulæ absent. The flowers are small, collected into spikes or racemes. The perianth is single and superior; the stamens are definite, exserted from the base of the sepals; the anthers are terminal and two-celled; the style is

single, and stigma often lobed. The fruit is hard and dry, sometimes slightly succulent, and one-seeded. The genera included in this order are *Santalum*, *Fusanus*, *Leptomeria*, *Thesium*, *Comandra*, *Hamiltonia*, and *Nyssa*. The *Santala*, or sandal-wood, especially the *S. album*, or true sandal, are fragrant. Hence the timber is much valued. It is made into musical instruments, cabinets, and curious boxes; no insect can exist it is said within its influence. Sandal-wood is extensively employed at the funerals of the Hindoos, and the nearer it is got from the root, and the deeper its colour, the greater is the fragrance.

SANTOLINA (Linnaeus). A genus of evergreen European shrubs, commonly called lavender-cotton. They belong to *compositæ*. The hardy sorts thrive in the flower border, and are propagated by division or cuttings.

SAPERDA (Fabricius). A very extensive genus of coleopterous insects, belonging to the family *Cerambycidae*, having the body of a cylindrical elongated form, with the thorax not spined at the sides. The species are in general very beautiful in their colours and forms, and are found upon flowers and the trunks of trees, within which the larvæ reside.

The tropical species are exceedingly numerous; there are six or eight British species, all of which are far from abundant; the type being the *Cerambyx cylindricus* of Linnaeus, which is black with pale femora.

SAPINDACEÆ. An important natural order, comprising nineteen genera, and above eighty-eight species. The order is divided into three tribes, viz. *Paulliniacæ*, *Sapindacæ*, and *Dodonacæacæ*. Nearly all the species have compound leaves and bunches of white flowers. The calyx consists of from four to five sepals, either discrete, or slightly adherent at the base. The petals are usually the same in number as the sepals, but sometimes one is abortive, and occasionally, as in *Dodonæa*, *Stadmannia*, and *Amirola*, they are altogether wanting. The stamens are definite, usually twice the number of the sepals. The germen is free, roundish, and formed of two or three carpels more or less distinct. The fruit is drupaceous or capsular, three-celled, or by abortion one-celled. The *Litchi* and *Longan* are common and favourite fruits in China, and are species of *Euphoria* or *Nephelium*. These fruits are sweet, with a sub-acid flavour, even when dried and brought to this country, but when fresh are delicious. Other species of *Nephelium* bear excellent fruits, but they are less agreeable than the preceding. *Melicoca bijuga*, *trijuga*, and *oliveformis*, are the honey-berries of the East and West Indies. Several other genera bear eatable fruits, but none are very superior, besides those mentioned.

SAPIUM (Linnaeus). A genus of tropical trees bearing monocious flowers, and belonging to *Euphorbiacææ*. The *S. aucuparium* succeeds in the stove if potted in light soil, and may be increased by cuttings.

SAPONARIA (Linnaeus). A genus of annual and perennial herbs, mostly natives of Europe. The flowers are decandrous, and the genus belongs to *Caryophyllacææ*. The species thrive in the common soil, and some of them, as the *S. calabrica* and *S. ocymoides*, are suitable plants for rock-work.

SAPOTACEÆ. A natural order containing eleven genera, and forty-four species, already described. They are trees or shrubs with a soft wood,

and lactescent juices. The leaves alternate, simple, entire, coriaceous, and petiolate, but destitute of stipules. The inflorescence is axillary, and the flowers regular and united: the calyx is free, and four to eight-cleft: the corolla is hypogynous in its exertion, regular, and cleft: the stamens are definite and distinct; some being barren and some fertile; the anthers are usually extorse; the germen is superior; the style one, and the stigma simple. The *Sapotacææ* are remarkable among lactescent plants for being in general innocuous. They yield great quantities of milky sap, which is used for alimentary purposes. Their fruit and seeds also abound in oil, which is solid like butter, and of a mild, pleasant flavour. Much of the palm oil of commerce is believed to be yielded by the *Bassia* or other *sapotacææ*. The flowers of *B. longifolia*, *latifolia*, and *butyracææ*, are all fragrant; a pleasant drink is made by infusing them in water, and this infusion, when fermented, becomes an intoxicating liquor, whence spirit is procured. The fruits of the several species of *Achras*, *Cryosophyllum*, *Minusapa*, and *Inocarpus*, are eatable, and more or less prized in different countries. The other genera not already mentioned are *Bumelia*, *Sersalisia*, *Sedrozylon*, *Nycterisition*, *Ochras*, and *Luosiana*.

SAPYGA (Latreille). A genus of fossorial hymenopterous insects, belonging to and being the typical genus of the family *Sapygidae* of Leach, which family is distinguished by having the body of an elongated form, the collar of the thorax large and transverse-quadrate; the legs short and slender, not ciliated nor spined, and the antennæ as long as the head and thorax. This family comprises the genera *Sapyga*, *Thynnus*, *Polochrum*, and *Scotana*; the first of which has the antennæ elbowed, thickened at the tips; the body long, cylindrical, and the eyes deeply notched in front. Entomologists appear to be at variance as to the habits of the species of this genus. St. Fargeau expressly states that they burrow in the mortar of walls or in wood (although not having spiny legs), for the purpose of constructing their nests, which they provision with other insects, and that he had himself observed *Sapyga* 6 punctata, carrying an insect which it let fall on being alarmed. Robineau Desvoidy, however, has more recently published some observations showing that it is parasitical, and Mr. Curtis in the British Entomology for the present month, has also made the same remark. The writer hereof has watched these insects on many occasions, and their motions certainly appeared to him to be those of parasitic, and not of working insects. There are two British species, the type being the *Sapyga prisma* of Latreille.

SARCANTHUS (Lindley). A genus of elegant flowering herbs, natives of China and India, belonging to *Orchidacææ*. These fine ornamental plants should be enveloped in damp moss fastened to a stump of wood, or enclosed in the outer fibrous coverings of cocoa-nuts, and placed in the air of a damp stove, kept at a high temperature.

SARCOCAULON (Decandolle). A genus of irregular-stemmed under-shrubs, natives of the Cape of Good Hope, and belonging to the natural order *Geraniacææ*. They thrive in light sandy moor-earth, and are readily increased by cuttings.

SARCOCEPHALUS (Afzelius). A fruit-bearing shrub indigenous to Sierra Leone, and there called the guinea peach. The flowers are pentandrous, and the plant belongs to *Rubiaceææ*. It is

readily increased by cuttings rooted in sand under a hand-glass in heat.

SARCOPHAGA (Meigen). A genus of dipterous insects, belonging to the family *Muscidae*, having for its type the blowfly (*Musca carnaria*), which see for an account of its habits.

SARGUS (Fabricius). A genus of dipterous insects, belonging to the family *Stratiomidae*, having the body elongated and depressed, the scutellum not spined; the head not produced into a nose in front. The species of this genus are very handsome flies, generally found during the summer months basking upon the leaves of various plants, and walking about slowly with the wings somewhat expanded; their flight is also slow, except during the hottest sunshine; at other times they are quite lazy. They are adorned with very brilliant metallic tints, especially green and gold. The larva of *Sargus Reaumurii*, has been observed both by Reaumur and Lyonnet; it is found in cow-dung, and is of an oval-oblong form, attenuated in front, and destitute of legs. It passes to the pupa state without shedding its larva skin. There are nine British species of this handsome genus (descriptions of eight of which have been published by Mr. J. Duncan in Jardine's Magazine of Zoology and Botany, vol. i.), the type being the *Musca cupraria* of Linnæus. Another species is the *Musca polita*, Linn., which, with several others, constitutes a distinct section, which Mr. Duncan has named *Chloromyia*, but which had been previously named *Chrysomyia* by Macquart.

SARRACENICÆ. A natural order of plants containing only one herbaceous genus, whence the title is derived. There are four species of *Sarracenia* already described, and remarkable for the singular form of their leaves, which are tabular and hold water, some of which have lids, which are said to shrink in dry weather. They are all natives of the North American swamps. In our collections they are grown in pots half filled with turfy peat, and having a coat of water-moss above: the pots are set in pans of water, and succeed best in frames kept in a shady place. The flowers are polyandrous.

SARROTRIUM (Illiger; *ORTHO CERAS*, Latreille). A curious little genus of beetles (*Coleoptera*), belonging to the family *Tenebrionidae*, having the antennæ thickened, and forming a spindle-shaped mass covered with rigid hairs, the last joint being much narrower than the preceding; the body narrow and depressed; thorax subquadrate. There is a single species (*Hyspa mulica*, Linnæus), of small size and black colour, found in sand-pits.

SATUREJA (Linnæus). A genus of herbs and under-shrubs, commonly called savory, and used in cookery as a seasoning, particularly the summer savory, which is an annual. The species are mostly natives of Europe, and belong to *Labiata*.

SATURNIA (Schränk). A genus of large lepidopterous insects, belonging to the section *Nocturna*, and family *Bombycidae*, and nearly corresponding with the Linnæan section of *Phalæna*, named *Attacus* (see *PHALÆNA*), having the wings extended horizontally, consisting for the most part of exotic species of very large size, and handsomely marked in their colours; the wings often being ornamented with a large glass or talc-like spot in the centre; such is the case with the immense atlas moth of China (*Saturnia atlas*), the *S. cecropia* from America and the *S. luna* of America (forming the subgenus *Actias* of Leach,

Zoological Miscellany), in which the hind wings are elongated into a pair of tails.

Another species is the *Saturnia promethea*, whose history we have detailed in the article *CATERPILLAR*, and of which, in the winged state, a figure is given in the article *MOTH* (p. 289, *ante*). This species is destitute of the talc-like spot. From time immemorial the *Bombyx mylitta* of Fabricius, and the *Phalæna cynthia* of Drury (both belonging to this genus), have been employed in the manufacture of silk (see the article *SILKWORM*). M. Latreille, who has devoted very considerable attention to this enquiry, states from a Chinese manuscript communicated to him by M. Hugar, that the caterpillars of these two species have been long known as the "vers à soie sauvages de la Chine," or wild Chinese silkworms. He also supposes that a portion of the silk which was employed by the ancients was procured by means of their commercial relations with the East, and was the product of these species.

Another species of this genus, known to collectors under the name of the emperor moth (*Phalæna, Attacus, Pavonia*, Linnæus), and which is the only British species belonging to this genus, has also been successfully employed in Germany in the manufacture of silk by M. Wentzel Hegeer von Bercholdsdorf, under an imperial patent. This handsome moth is by no means rare, and varies in the expanse of its wings from two and a half to three and a half inches, and has the wings clouded and fasciated with grey, with a large central eyelet. It proceeds from a large caterpillar of a fine green colour with black bands, the latter being ornamented with red and yellow hairy warts. It is a very general feeder, and constructs a very interesting cocoon for the purpose of undergoing its transformations, of a brown colour and shaped somewhat like a flask. It is composed of a solid tissue of layers of silk, almost the texture of parchment; but at the narrow end it is composed of a series of loosely attached longitudinal threads converging like so many bristles to a blunt point, in the middle of which is a circular opening through which the moth makes its escape, the threads readily yielding to pressure from within, and acting somewhat upon the principle of the wires of the opening to a rat-trap, or the willow cricks of an eel trunk. In order, however, to guard against the danger which might arise from the opening permitting the ingress of Ichneumons or other enemies, the caterpillar constructs within the funnel-shaped mouth a second funnel formed of a similar series of thread converging to a point, without the smallest opening being left, and its arched struc-

Section of the Cocoon of the Emperor Moth, showing the internal dome, *a*; and the external aperture, *b*.

ture rendering it impenetrable to the most violent efforts of any external enemy, whilst it yields to the slightest pressure from within, and allows the egress of the moth with the utmost facility, immediately resuming its former appearance, so that it is impossible at first to conceive how it is that the moth can

have made its escape from an entire cocoon. Meinencken* has also suggested that the pressure of these converging threads upon the abdomen of the moth as it emerges from the cocoon has the effect of forcing the fluids to enter the nervures of the wings, and give them the proper expansion, having noticed that moths produced from chrysalides taken out of their cocoons were crippled in their wings.

SATYRIUM (Linnaeus). A genus of tuberous-rooted herbs, natives of the south of Africa. The genus belongs to *Orchidaceae*, and, like the rest of the order, bears curious, though not very showy flowers. They grow in sandy peat earth, and require the protection of a frame in winter.

SAWFLY (*SERRIFERA*, Latreille). The English name for a very extensive group of hymenopterous insects, composing the Linnaean genus *Tenthredo*, and modern family *Tenthredinidae*, distinguished by their large wings with many cells, the abdomen united to the body by its whole breadth, and terminated on the underside by a pair of organs (ovipositors), which are employed in the act of depositing the eggs something in the same manner as the common hand-saw of mechanics, whence the popular name of the family. The construction of this pair of instruments is, however, so much superior to that of the hand-saw, and exhibits so admirable an instance of contrivance in its design for a determinate purpose, that a minute account of its structure will not be uninteresting. Of course, the particulars cannot be observed without the assistance of a microscope, or high-powered lens; and when these are employed, it will be found that almost every species varies in some one or other particular. The eggs of these insects are deposited in the bark of trees, the twigs of various plants, or within the epidermis of the leaves, in which a slit is first formed, into which the eggs are successively introduced. The eggs have indeed somewhat of an analogy to vegetable nature, as, for a certain period, they increase in size, in consequence, as is supposed, of imbibing the fluids of the plants into which they have been introduced by the saws. The dorsal segments of the abdomen are deflexed at the sides in these insects, the terminal segment being produced at the base beneath, towards the base of the abdomen, forming a groove on the underside within which the saws play, being, moreover, protected by two distinct scaly plates. When the insect, therefore, is disposed to make use of its saws, it widens the groove, and extends what at first sight appears to be a single membranous piece, but which is very soon perceived to consist of two plates, each formed of two distinct portions, constantly applied against each other when at rest; the lower half of each of these instruments, that is, from base to tip, is the saw, and the upper half of each constitutes the supports of the saws, being formed with a groove somewhat like the structure of a clasp knife; in each of these grooves, therefore, one of the saws plays backwards and forwards, the muscles at its base acting as the moving power, and when these four pieces are brought into contact, a central space is produced which serves for the passage of the egg. The back, or support of each saw, indeed, at first sight appears very similar in its construction to the saw itself, being of equal length

and breadth, with similar transverse, or rather slightly oblique ridges; but a more minute examination shows them to be unfitted for action as sawing instruments. These ridges or oblique channels correspond in number with the number of teeth in the saw. It will be easily conceived that, from the support given to the supporting piece by the corneous plate of the abdominal segment, it is well fitted for enabling the saw to work backwards and forwards. In the carpenter's saw there is somewhat of the advantage of a double edge (which we here find produced by the presence of two saws), because the teeth of the carpenter's tool are alternately directed to the right and to the left; and the groove between the two lines made by the teeth, which is called the *course of the saw*, is represented in the sawing of the sawfly by the action of the two saws having straight teeth. It will therefore be probably asked, where is the necessity for two saws, when even the ingenuity of man has effected a similar purpose with only one saw? and if the action of the insect had no other object than that of sawing the plant, there might be perhaps ground for the enquiry. But the insect has another and far more important object to perform, namely, the depositing of its eggs in the groove made by the saws, which could not be done by a single saw. At first sight the saw appears to be composed of simple teeth, but the application of high-powered lenses proves that one of the edges of each tooth is itself furnished with very minute teeth, thus combining the property of a rasp or file, in their lateral action, with that of a saw in their vertical movement. Moreover, the sawfly has the power of working the saws alternately, a peculiarity necessary, because each works in the same channel, and not, like the compound saws of artificers, in distinct lines. More highly magnified powers, also, show that even the membranous sides of the saws are furnished with an infinite number of minute points, which, in all probability, serve to irritate still more forcibly the edges of the wounded part of the plant, causing it to produce a greater supply of extravasated fluids, which is serviceable for the development of the egg.

A, extremity of the abdomen of the Sawfly, showing the two saws *c* and their supports *d* extended; *a*, the terminal joint of the abdomen; and *b*, the two internal horny sheaths. B, a small portion of one of the saws very highly magnified.

After the groove is rendered sufficiently deep, the saws are made to conduct an egg into the place prepared for its reception, immediately after which a drop of frothy fluid is introduced into the hole over the egg, of which the probable use is to close the wound. Each groove contains but a single egg, and there are accordingly sometimes as many as a couple of dozen of grooves to be made; these are placed in a line on the same branch, six of them occupying

* Quoted by Kirby and Spence, from whom this account is abridged.

the insect (according to Reaumur) about ten hours and a half in their construction. The grooves, at first, are scarcely perceivable above the surface of the branch, but, by degrees, become more and more convex by the increased size of the egg, a circumstance of considerable interest, and quite at variance with the analogy of the eggs of the majority of insects and birds. In some species, however, the eggs are deposited together in a single large groove, and in some species the parts of the leaves wounded by the sawfly produce galls (as in *Nematus interiorius*, &c.) similar to those formed by the true gallflies. These galls are variable in their form and substance, being either woody or pulpy, and either of the ordinary form, or resembling a small fruit. In these species the larvæ hatched from the eggs continue to reside within the galls, either alone or in company, but in general the larvæ of the sawflies are external feeders, devouring the leaves of trees and plants. These larvæ, from their general form, and the number of their legs and prolegs, bear a very great resemblance to the caterpillars of lepidopterous insects, so that they are ordinarily termed by the French naturalists *fausses chenilles*, or false caterpillars. The number of their legs differs from that of the true caterpillars, which have from ten to sixteen; whereas these false caterpillars have either only six, or from eighteen to twenty-two. Many of these false caterpillars have the habit, when alarmed, of rolling themselves up in a spiral manner, like an *Iulus* and others, whilst feeding, generally elevate the hind part of the body in the air, giving themselves a very droll appearance, and twisting their tails about in all directions. In order to undergo their transformations to the pupa state, they construct a cocoon, partly of silk and partly of earth, glued together with a gummy secretion, which they emit from the mouth, and within which they remain for a great length of time without throwing off their larvæ skin. The pupa is incomplete, and closely resembles those of other hymenopterous insects in its general form. Many of these insects are very obnoxious to the agriculturist and horticulturist. Thus the larva of one species preys upon the upper surface of the leaves of barley, and causes it to wither. Another species feeds upon the rose, *Athalia Roseæ*, (Linnaeus); and the writer hereof has discovered the preparatory states of a species of *Lyda* upon the same plant, of the leaves of which the larvæ construct a very curious case, in which they reside; and the gooseberry is occasionally stripped of its leaves by the larvæ of another small species, which is found upon it in very great profusion. This larva is of a greenish colour, covered with minute black tubercles, and at first feeds in society; but no sooner have they consumed the leaf upon which they were born, than they separate, and the work of devastation is carried on to such an extent, that in a very short time not a leaf remains on the tree, and the crop of fruit is entirely consumed. Fumigation, by means of sulphur or burnt leaves, may be successfully employed.

Another species, *Tenthredo cerasi* (Linnaeus), feeds, in the larva state, upon the leaves of the cherry and some other fruit-trees. At this period of its existence it has scarcely the appearance of an insect, being covered with a slimy secretion, which causes it to resemble the feces of some small bird (and thus to escape from the insectivorous birds), and which is aided by its sluggish habit, as it does not stir until it

has entirely consumed the epidermis of the leaf in its immediate vicinity. In North America the cherry-pear, apple, and plum, are occasionally attacked by another insect very nearly allied to the preceding, and which is there known under the name of the slugworm. In 1797, they entirely covered the smaller trees to such an extent that the atmosphere in the immediate neighbourhood was charged with a sickening odour. Twenty or thirty were to be seen on a single leaf, and, many trees being completely stripped, were obliged to put forth fresh foliage, thus anticipating the supply of the succeeding year, and cutting off the prospect of fruit. (*Peck, Nat. Hist. of the Slugworm*, quoted by Kirby and Spence).

But the most destructive insect of the present family is one of which the larva is commonly known under the names of the "blacks" or "niggers," and which have, during several of the past years, entirely consumed many of the turnip crops in the south of England. About twenty years ago they were observed to be equally abundant as well as in the year 1788. It would therefore form a very interesting and not wholly useless subject of inquiry, to endeavour to ascertain what identity of natural causes existed in those years in order to permit the development of the insects to so great an extent. The admirable meteorological tables which are now published from time to time must evidently be of great service, by taking the averages in prosecuting such an inquiry. These larvæ are about half an inch long, and feed upon the fleshy part of the leaf of the turnip, leaving the fibres so clean that the leaves are reduced to perfect skeletons; when disturbed, they roll themselves up in a spiral manner; they are of a slaty black colour above, with a pale dirty lateral stripe, which is also the colour of the under surface. It has been observed that they do not attack the Swedes or rape. The most successful remedy which we have yet heard of has been to turn in a great number of ducks among the turnips, accompanied by a boy who brushes the plants with a long stick, which causes the grubs to fall, when they are greedily devoured by the ducks, which are very fond of these palatable morsels. When full-fed they descend into the earth, form an oval cocoon, and therein undergo their transformations. The perfect insect (*Athalia centifolia*) is about a quarter of an inch long, with the head and antennæ black, the abdomen and legs bright orange, the thorax also orange with dark spots at the base of the wings. In this state indeed it is very conspicuous, and an intelligent farmer, by going over his fields, would not only be able to foresee the danger which would ensue to his crops if left untouched, from observing the presence of these flies amongst his plants, but also probably to some extent be enabled to guard against the danger by employing children to capture and destroy the forerunners of these nigger caterpillars.

We shall treat of these insects technically, under the title TENTHREDINIDÆ.

SAXICOLA (*Chat*). A species of birds belonging to Cuvier's dentirostral family of *Passeres*, and to the small-billed section of the family, and of course insectivorous in their feeding. The characters of the genus are: the bill slender and nearly straight, a little broader than high at the base; the upper mandible with a ridge which advances on the point, and is covered at the base with some hairs; the mandibles awl-shaped and pointed, and the upper one curved

Q Q

at the tip. The nostrils lineal, oval, half covered by membrane. The tarsi in general long; the toes four, three to the front, the exterior front one united to the middle one at its base; the claw on the hind toe short and very crooked. The first quill very long, and the third and fourth the longest in the wing. They have not much song, but they are very handsome and hardy birds. Their habitations are various; some in the woods, some in the bushes, some in the bare uplands among stones; but they are all insectivorous, and with us they are all migrant. The species are numerous, and met with in various parts of the world; but we must restrict this notice to a few of those which are most interesting to British readers.

THE WHEAT-EAR CHAT (*S. Œnanthi*) is a migrant, departing from Britain in the fall of the year, and returning again pretty early in the spring; but it is one of the most numerous of the genus, and indeed more generally distributed over the wild and half-cultivated parts of the country than almost any other bird which comes to us during the summer. It is not a bird of bowers, or even of bushes, but of the open fields, where these are not in a state of high cultivation. The particular form of the claw on the hind toe unfits this bird for walking upon, or rising from the grassy sod, as the lark does; and consequently it is found only on the bare ground. Its perch is on the clods, or on a stone; and the nest for its young is under the same. The flight of these birds during the nesting time is short and low, and the song of the male, though sweet, is audible only at a very short distance. The usual note, which is like the tapping of one pebble against another, seems to be in some way connected with the feeding of the bird, but in what way is not known. This is the largest British species, as well as the most abundant. It is six inches in length, or rather more, and nearly an ounce in weight. The naked parts outside, and also the gape, are black, and so are the quills, the middle tail feathers, and the tips of the lateral ones. The breast is buff-coloured; and all the rest of the under part and the rump white. One knows not for what reason, but this bird is much persecuted in many parts of the country; and in the southern parts great numbers are caught and eaten in the autumn, at which season they become very fat.

THE WHIA-CHAT (*S. rubetra*) is about five inches long, and half an ounce in weight. It is a migrant, coming to the south of England in April, and getting gradually north, though not to the extremity of the country, or so far up the hill as the wheat-ear. Its place is on the margins of the cultivated grounds, wherever it can find cover for its nest, either in a bush or a tuft of tall grass; but it prefers the former. Furze bushes are favourites with it, as they are not easily entered by any predatory bird from above, or by a large bird from any quarter. The magpie and the crow are the great plunderers of nests in these wild places; but neither of them is very fond of taking a furze bush by storm, bristling as it does with spears innumerable. The bird itself is just as safe. It usually perches on a lofty twig, darting like lightning on any fly that comes within the range of its keen vision; and the moment that any danger appears it drops into the bush, where it makes its way to the place most distant from that at which it entered. In situations favourable to their habits they are not rare; they make their appearance rather early

in the spring, and when the cold weather begins to set in they depart from all the northern parts of the country, and only a few of them remain in the counties bordering on the channel. The number that may do so must, however, vary with the season; and as this is the case with all birds that have short migrations, it is never easy to draw the line between total migration and partial residence.

In the male bird, the upper parts are blackish brown, with dusky and white markings on the breast; the breast is pale, passing into dull yellow on the belly, and white on the vent feathers. The female has the white on the head less conspicuous; and the young birds have the brown parts mottled with white and grey.

They are birds of more feeble make than the other chats, and their wings are not formed for long flight, so that they are rare in the south-west of England where the channel is broad.

THE STONE-CHAT or CHUT (*S. rubicola*). Though this is by no means the most plentiful species in Britain in the summer, it is the only one which is decidedly a permanent inhabitant of Britain. It is found on the dry moors, downs, and commons, where there are bushes; and, like the last mentioned one, it is particularly partial to furze. It is a very pretty bird, handsome in shape, rich but not gaudy in its colours, and the male has a pleasant song. That song is indeed not very loud and varied; but the place where it is heard, and the early season at which it is given, tend to heighten its effect. It sings before any other note of bird but its own is heard; for the call of the grouse ceases at daybreak, and the crow does not come till there are nests to plunder.

The bill, which is stout at the base, a little bent, and pointed at the tip, is black, and so are the head, throat, and upper neck, in the male. The rest of the upper plumage is dusky with brown margins to the feathers. The rump, a large patch on the greater coverts, and another on the side of the neck, are white. The breast is of a rust colour, passing into dull yellow on the belly, and white on the vent feathers. In winter the black on the head becomes mottled with rusty brown, and the rust-colour on the breast fades to a dull white. The female has the whole upper part brown and the under pale brown, without any white on the rump. The colours of the female change very little with the season.

The chats, or at all events birds which very closely resemble the chats in their economy, are numerous in some parts of the world; and the climates in which they are found, together with the localities which they occupy in this country, and the food upon which they subsist, point them out as having a well-defined place in nature. They hold an intermediate station between the wagtails and the fly-catchers, being farther from the water than the first, and farther from the wood than the second. All the three subsist in great part upon full-grown insects, which they capture by lying in wait, and not by chase. The number that pass among the bushes is greater than one would suppose from the dryness of the place, for many of the insects which arrive there pass their larva state in the earth, indifferent of what may be on the surface. All places of which dryness and bushes are characteristic are favourable for chats; and therefore they are numerous in Southern Africa, and in all countries that have the same extreme of drought during part of the year. Most of the insects of such places

are of small size, and they pass so rapidly that they could hardly be taken by the swallows and swifts. These fly rapidly, no doubt, but some time elapses before their long wings can get the proper momentum. Hence they are fit for such places only as abound with aerial prey. The most vigorous of them would be worn out before they could make half a meal; and therefore there are set over the winged insects of these places birds which have keen eyes, can get readily on the wing, fly rapidly for a short time, and fly in every direction. All these are characters of the chats, and there are no birds in the class better suited to their places.

SAXIFRAGEÆ. A natural order comprising ten genera and one hundred and forty-two species, chiefly alpine herbs. Their leaves are opposite or alternate, in general, simple, and without stipules, but occasionally compound, and furnished with interpetiolar stipules; the calyx consists of five sepals, more or less connate, and joined to the germen; the germen is sometimes inferior, sometimes half-inferior, and sometimes free; the petals are equal in number to the sepals, exserted from the tube of the calyx, and alternate with the lobes; the stamens are perigynous, proceeding from the calyx; the filaments are awl-shaped, and the anthers ovate and two-celled, opening by pores or chinks; the germen consists of two carpels; the styles equal to the carpels and persistent; the stigmas clubbed. The fruit is a two-valved capsule, opening either from the base or apex.

Saxifraga is a very extensive genus, and various attempts have been made to break it up into several genera, but their affinity is so close, and the gradations so complete, that it seems preferable to consider most of them only as subgeneric groups. The genera included in this order are the following: viz., *Saxifraga*, *Heuchera*, *Tiarella*, *Astilbe*, *Mitella*, *Tellima*, *Chrysosplenium*, *Adoxa*, *Hydrangea*, and *Galax*.

SCABIOSA (Vaillant). An extensive genus of annual and perennial herbs, found in all parts of the old world. The flowers are tetrandrous, and the genus ranks among the *Dipsacææ*. A few of them are British weeds; the East Indian annual sorts are admitted into our flower gardens; and the African sorts are shrubby.

SCÆVOLA (Dr. Brown). A genus of undershrubs from the East and West Indies, and herbaceous perennials from New Holland. They belong to the class *Pentandria*, and to the natural order *Goodenovicææ*. The stove species being somewhat succulent, must not be over-watered; both these and the greenhouse sorts are propagated by cuttings.

SCALARIA (Lamarck; *TURBO SCALARIS*, Linnæus). This mollusc has been commonly called the wentletap, a corruption from the German word *wendle-treppe*, a winding staircase. At one period large sized examples of it were extremely rare, and no shell ever produced a higher price, the enormous sum of one hundred guineas having been given for a specimen, which, at the present time, would find no purchaser at as many shillings. The writer of this article has had an opportunity of seeing numbers of these shells, many of which were sold at high prices, but no one produced more than fifteen guineas. This shell is now by no means rare of an ordinary size; it seldom exceeds two and a half inches, but when it reaches three and a half, it is of very rare occurrence, and still bears a price out of all proportion to the

smaller specimens. Linnæus, in this instance, exhibited that want of observation and correct judgment which so frequently marks the generic arrangement of his conchological system; he classed this mollusc with the genus *Turbo*, and subsequent writers have blended it with the modern genus *Cyclostoma*; it has, in fact, a circular aperture, but its habitat is different, and its turreted form unlike that genus; another distinguishing distinction is the longitudinal elevated ribs, which are never connected together entirely; these ribs are only the thin reflected margins of previous terminations of the aperture, each one exhibiting the growth and addition made to the shell by its inhabitant at successive periods of enlargement, and these would, if it were possible to mark them from time to time in their native element, demonstrate the age of the shell, a circumstance now involved in the greatest obscurity, and merely a matter of conjecture, no parity of reasoning bearing upon that point with any degree of satisfactory conclusion. The *Scalariææ* are marine shells, their spire is more or less elongated in the different species, but in all the succeeding whorl is always larger than the preceding, which occasions the turreted form of these shells to differ from the cylindrical shape of the pupa, to which in some other respects they may be said to possess a resemblance, particularly in having numerous ribs on the whorls. The aperture of the *Scalaria* is round or nearly so, sometimes a little more depressed on the inner than the outer side; the edge of it is thickened, sharp, and outwardly reflected at right angles, and there appears a very slight indication of a groove or canal on the columella side not mentioned by Lamarck or other writers; they possess an operculum, but it is extremely uncommon to meet with it, as the animal is rarely imported with its shell. The *Scalaria pretiosa*, which, from its name, implies its estimation, is very singular for its umbilicus and the separation of its spiral whorls, which appear like an attenuated tube spirally evolved round a cone. The whorls are drawn out, and some examples have been met with in which the whorls do not touch each other in any sense. They are, however, ordinarily touching or connected together by the longitudinal ribs formed of the previous terminations of the aperture. Several species are known, both recent and fossil, but their distinctions are none of them so marked with each other as the *Scalaria pretiosa* is with them. In such examples as present the whorls totally unconnected with each other, the so called ribs not being in any way essential to their support, an alliance may be traced to the genus *Vermetus*, but the animal differs in many respects: it is spiral, the foot short, oval, and inserted beneath the neck; there are two tentacles terminated by a thread carrying the eyes at the extremity of the larger end. The Chinese and Japanese seas produce the rare species we have above described; but the *Scalaris communis* is abundantly found on our own coast, and in other northern latitudes. The late Dr. Leach named that species whose whorls are totally disjunct *Acyonea*, but we rather view such an occurrence as a sport of nature, than caused by any specific distinction, similar luscæ being observable in many other mollusca, and even in the genus *Helix*, though they are extremely uncommon.

SCALLOP SHELL is the familiar name of the *Ostrea maxima* of Linnæus, the *Pecten maximus* of Lamarck. Under its English name it is so well

known as an edible in our fish markets, that a minute description is needless. The animal is precisely similar to that of every other species of *Pecten*; as a delicacy for the table it is much admired by some gastronomers, and we will only add a few remarks upon what may be termed its historical character. The scallop shells were abundantly found on the shores of Palestine, and the chivalric crusaders of olden times, as well as pilgrims journeying to the Holy Land to expiate some sin, or to accomplish some thoughtless vow to their mistress, affixed one of the valves to some portion of their dress, to indicate beyond all doubt that they had crossed the sea in pursuit of their pious purpose; those who survived the perils of their pilgrimage preserved this emblem as an armorial distinction, still to be found in the heraldic quarterings of many English and other families of ancient descent. Our native poets and minstrels, with the troubadours of old, often sang of this distinctive honour, and Macpherson informs us that in the dreamy days of Fingal's cloudy songs, these shells were introduced into the feasts of heroes as the cup of their festive libations, by the Gaelic name of *sligha creachin*, or the drinking shell; and, to the present time, the valve of a large species of scallop is used, for the less classic but more useful purpose of skimming milk by the hands of the industrious daughters of Scotia, in the Hebrides, and other parts of Scotland. The ghosts of antiquity appear to have been content with a very moderate libation in honour of their heroes, as we cannot imagine the draught could have been long or deep, which the scallop shell supplied; but of their size, or the frequency of their being replenished, Fingal does not speak. Temperance societies were certainly not introduced at that period, and if the many tongues of Fame are to be believed, they have not yet made great progress in our sister kingdom; as a step to their completion we, however, recommend the *toddy* lovers to commence their reformation by drinking out of scallop shells.

Many fanciful tales are related in the poetical language of modern-would-be naturalists of the scallop being capable of expanding one valve to answer the purpose of a mainsail, and thus floating in fleets on the calm surface of the ocean tide; we are, however, sceptical, and the fact must rest upon better evidence than a poet's dream ere we lend our faith to it. The genus *Pecten* certainly possesses the faculty of springing on the sandy shore by the contraction of its foot, and it is possible that its progress through the deep sea may be effected by the sudden expansion and contraction of its valves acting as a propelling force against the watery medium; but we are yet ignorant of their habits of life to that extent. The flimsy tissue of fiction has been thrown around many objects of natural history, and it is difficult to forget our nursery tales, but the march of intellect will divest them of their marvellous attributes; and it may be added, that many of the tales of antiquity, when shorn of these, are found to possess some foundation in truth, though so strongly distorted by fictitious additions and ignorant superstitious credulity: thus, seals may become mermaids, the eider-duck a phoenix, and the anafifa a soland goose; not to enumerate many other instances in the annals of natural history illustrative of the poetic effusions of vivacious minds.

SCARABÆUS (Linnaeus). Under this generic name Linnaeus comprised a very extensive tribe of coleopterous insects, placed by him at the head of the

insect tribes—and answering to the *Petalocera* of Dumeril—as well as the Latreillian section *Lamellicornes*, (including, however, the *Lucanidæ*), under which latter name we have given a sketch of the modern distribution of this interesting group. By the French entomologists of the present day, as well as by some English writers, the name is still retained generically, for the gigantic insects placed by Linnaeus at the head of the genus, such as the elephant and hercules beetles, &c., of the latter of which a figure is given in the article *DRNASTES*, which is the name given to them by MacLeay and Kirby, whilst by the Germans these gigantic species are called *Geotrupes*. Mr. MacLeay, on the other hand, gives the generic name *Scarabæus*, and the sub-generic one *Helicocantharus*, to the sacred beetles of the Egyptians (see *HELIOCANTHARUS*), and the name *Geotrupes* to the shardborn beetles (see *GEOTRUPES*). Nothing can be more troublesome than this uncertainty and constant changing of generic names, which cannot however be remedied so long as naturalists are not agreed upon the most fundamental principles of zoological nomenclature. We have already given under the article *LAMELLICORNES* the chief characters and disposition of this group.

SCARITIDÆ, or more properly SCARITIDÆ, a sub-family of the predaceous land-beetles *Carabidæ*, having the elytra entire and rounded behind, the antennæ elbowed, the thorax separated from the base of the elytra by a distinct peduncle. The anterior tarsi of the males are not dilated, and the anterior tibiae dilated and palmated, or deeply notched. This latter character indicates the chief habits of the group, that of burrowing into sand in the neighbourhood of the sea, or in the banks of water. They chiefly frequent hot climes, some few, and these of small size, being found in this country. They keep close in their retreats during the day, but come abroad at night to feed upon any insects or dead matter which they can find. M. Lefebure de Cerisy, a distinguished entomologist at Marseilles, has employed the following method for capturing the *Scarites Pyracmon*. During the day he deposits a quantity of dead cockchafers (*Melolontha vulgaris*) in those situations where the *Scarites* is probably an inhabitant, and then examines the insects at night with a lantern, when he generally meets with them in the act of feeding upon their prey. The species are for the most part black and very glossy. The genera belonging to this sub-family are: Enceladus, Siagona, Coscinia, Melænus, Carenum, *Scarites*, Acanthoscelis, Oxystomus, Oxygnathus, Camptodontus, Pasimachus, *Clivina*, *Dyschirius*, Ozæna, Scapterus, Carterus, Odogenius, Pachycarus, Morio, Ditomus, *Aristus*, and *Apotomus*. Those printed in italics contain British species.

The typical genus *Scarites* is distinguished by having the fore tibiae palmated, the mandibles strong toothed, and the thorax semilunate. There is only one British species (*Sc. Beckwithii*) of which three specimens only have been noticed, one of which was captured on the Yorkshire coast.

In *CLIVINA* (which see) the thorax is quadrate, and in *Dyschirius* globose. The following observations upon the habits of a large species of the latter genus have been published by the Rev. Mr. Rudd in the Entomological Magazine. This species occurs in great abundance in the sandy shores of the estuary of the Tees, and in turning up the sandy tracks or

burrows of a small burrowing staphylinideous insect (*Hesperophilus arenarius*) above high-water mark, he found their ferocious enemy the *Dyschirius* pursuing its work of destruction. These *Dyschirii* burrow after, seize, shake, (as the *Cicindela campestris* does its prey) and devour the luckless *Hesperophili*; and so intent are they on their purpose, that he frequently observed them shaking their victims after they were brought to light.

SCATOPHAGA (Meigen). A genus of dipterous insects belonging to the family *Muscidae*, having the legs formed for walking, and spinose, antennæ inserted between the eyes; the wings considerably longer than the abdomen, head nearly conical in front, and rounded behind. The type is the *Musca Merdaria* Linn. or the cow dung-fly, an insect which appears early in the spring, and which is constantly to be found upon the excrement of various animals, and it is in such situations that they deposit their curiously formed eggs, of which a figure is given in vol. ii. p. 893, fig. 5. The perfect insects are generally of a yellowish brown colour. There are a considerable number of species nearly resembling each other.

SCHEDONORUS (Beauvois). A genus of grass formerly called *Festuca* in English botany. Several of the species are agricultural, and form a part of the mixture of seeds employed in laying down permanent pastures.

SCHIZANTHUS (*Flora Peruviana*). A genus of fine flowering annuals, bearing diandrous flowers, and belonging to the natural order *Scrophularinæ*. Though natives of Peru, the species flower and ripen seeds in our open borders, as well as if in their own climate.

SCHIZOPODA (Latreille). An order of crustaceous animals, chiefly characterised by having the legs cleft from the base into two appendages, giving the appearance of double legs. The species of which this order is composed have been but little investigated, with the exception of the opossum shrimps *Myris*, which see. The other genera are *Mulcien* *Cryptops*, and probably *Nebalia*, *Zoe* and *Condylura*.

SCHÆNUS (Linnæus). A genus of bog plants, natives of Europe and Australia. It belongs to *Cyperaceæ*; not in cultivation, but useful for making bands for tying up goods.

SCHOTIA (Jacquin). A genus of African evergreen shrubs belonging to *Leguminosæ*. The flowers are beautiful, and the species are well worth cultivation in the coolest end of a stove.

SCHUBERTIA (Mirbel). This is one of the most beautiful of trees. It is the *Cupressus disticha* of Linnæus, the *Taxodium distichum* of Richard, and the *deciduous Cypress* of English authors. It is one of the *Conifera*, and, like the others, is usually raised from seeds.

SCIENOIDEÆ. The third of the families into which Cuvier divides the spinous-finned fishes; and one, the genera and species of which are so numerous that it would form an extensive study in itself. These fishes resemble the perch family in many of their characters, but still they are distinct. They have the body scaly, but the scales are not so large as those of the perches; they have two dorsal fins in some; the spinous rays of the anal are slender; but the principal distinction is in the teeth. There are none on the vomer or the palatal bones; their gill-covers are toothed in the margin, and furnished

with spines; and very often the bones of the face are enlarged with cavities, which produces a thickness in the appearance of the muzzle. The most obvious division of them is into those with two dorsal fins, and those with one only.

None of the family can be said to be natives of our seas, but there is an occasional straggler of some of the most celebrated ones. Many of them are fishes of large size, very powerful swimmers, and much esteemed as food. They are abundant in the Mediterranean and in the warmer parts of the Atlantic, where they are among the most valuable fishes for the table, and consequently the capture of them is an employment of considerable profit. We can afford room to notice only two of the genera, and a single species of each, merely naming the others.

SCIENA. These have the head tumid, produced by cavernous bones; two dorsal fins, or one with a large notch, and the soft rayed part occupying a greater length of the back, than the spinous part; the whole head covered with scales; and the air-bladder with a curiously fringed margin.

THE MAIGRE (*S. Umbræ*). This is a Mediterranean species, attaining the length of six feet or upwards, and seldom caught of less than three feet. It is supposed to spawn in the south part of the Mediterranean, as small ones are met with on the shores of Egypt, but not on the shores of Italy, the south of France, or Spain. The general colour is silvery grey, paler on the belly, and inclining to brown on the back. The fins are reddish brown. They are very restless fishes, always moving about in small parties; and it is said they make a sort of grunting noise, which betrays them to the fishermen, even though they are twenty fathoms under the surface. A curious circulation of the head of one of these fishes from party to party at Rome, is recorded by Paulus Jovius. The fishermen gave it to the conservators; these gave it to the nephew of Sixtus X.; he presented it to a cardinal; the cardinal gave it to his banker, and the banker to his courtesan. This was, of course, the *ne plus ultra* of transfer for the head of a fish; but it is not the most curious part of the matter; for a "dining" gentleman scented it all the way, and at last shared in the feast. The head was accounted the prime part, and the conservators alluded to were the magistrates who had charge of the city.

Its rambling habits often lead it as far to the north as the extremity of Britain; and of late years several large ones have been caught on the south coasts. We shall quote Mr. Yarrell's account of one of them. "In the month of November 1834, a specimen five feet four inches long, was taken by some herring-fishers off the Kentish coast, and brought to the London market. This fish was bought by Mr. Groves of Bond Street, who very kindly gave the skin to the Zoological Society for preservation. Part of the flesh was eaten by several persons, and by all reported to be good, particularly by those who prepared their portions by stewing. When plain boiled only, it was rather dry and tasteless. The two hard bones usually found just within the sides of the head in fishes, are larger in proportion in the *Maigre* than in any other fish, and were supposed, the older writers say, to possess medicinal virtues. According to Belon, they were called colic-stones, and were worn on the neck mounted with gold, to secure the possessor against this painful malady. To be quite

effectual, it was pretended that the wearer must have received them as a gift; if they were purchased, they had neither preventive nor curative power.

The general aspect of the *Maigre* is heavy and lumping; but it is a remarkably well-finned fish, and gets quickly through the water. The family are inhabitants of the pure water, rather than bank fishes.

UMBRINA. This genus resembles the former in the main features; but it has a barbule at the point of the lower jaw; the teeth are smaller and more numerous, and the rays of the anal fin are stouter.

The common *Umbrina* (*U. vulgaris*), is a species of this genus, very common in the Mediterranean, and one solitary stray at least has found its way to the British coast. This was to the coast of Devon in 1827; but none, even of the most experienced fishermen, had any name for it.

It is a very beautiful fish in the colours, and described as being excellent. The following cut will give some idea of it.

The ground colour of the back is golden yellow, more or less bright according to the season, and condition of the fish. The oblique bands are silvery white and steel blue; and the under part is white. The irides are silvery, and the pupils of the eyes deep black. The head is short and blunt; the upper jaw the longest, with three mucus pores at the extremity; and the lower one flat, and with a short barbule at the junction of the maxillary bones. The teeth are small but numerous, forming a broad band like a rough pavement in each jaw. The rays in the fins are: ten in the first dorsal, and twenty-two in the second; seventeen in the pectorals; one spine, and six soft rays in the ventrals; one and seven in the anal; and seventeen in the caudal. The lateral line is high on the side, and parallel to the outline of the back. The fins on the back are brown, with two bars across; the caudal fin is red; and all the remaining fins are nearly black.

As a fish for the table it is superior to the maigre, notwithstanding the celebrity which that has acquired. It is generally about two feet long; but some specimens weigh forty pounds, it being a very deep and thick fish in proportion to its length. The flesh is white and well flavoured. Altogether it is a much more handsome fish than the maigre; and it is still more common. Its food is various,—small fishes, mollusca, and, as it is said, sea-weed. It is much more common on the Spanish coasts than the other; is well known at Gibraltar, and *Umbrina* the Spanish name for it. It is said to occur not unfrequently in the Bay of Biscay.

Otolithus. The fishes of this genus have no barbule on the jaw; they have the teeth very large and crooked; and the anterior part of the swimming bladder is divided into two branches. They are all or chiefly natives of the warm seas,—the tropical parts of the Atlantic, and the Indian Ocean. One is

the stone perch of the Coromandel coast, another the Lutjan of the West Indies. They are in fact numerous, and most of them are esteemed as food.

Carvina. This genus have the teeth small and i a band like those of the *Umbrina*, but no barbule; they also differ from the preceding genus, in having the second ray of the anal fin thick and strong. One species is very abundant in the Mediterranean, and there are various others in the Indian and American seas.

Johnius. The fishes of this genus very much resemble those of the last mentioned one, only they have the second spinous ray of the anal fin shorter and weaker. They are natives of the warm seas, and are caught on the shores of India, Africa, and America. Their flesh is white and light, highly esteemed, and can be had in abundance, so that they are very valuable fishes to the inhabitants of those countries.

Pagionias (Drummers). These fish get that name because the sound which they utter resembles that of drums at a distance. They are very like the genus *Umbrina*, only instead of one barbule on the under jaw they have a number. One species, *Fasciatus*, is of a silvery colour, with brown bands, which are most conspicuous on the young. It has the bones of the pharynx thickly set with large and flat teeth. It is an American fish, and grows to a size not inferior to that of the maigre.

SCILLA (Linnaeus). A beautiful genus of bulbous stemmed plants, mostly natives of Europe. The flowers are hexandrous, and the genus belongs to *Asphodelia*. The squill is a native of the southern parts of Spain, Italy, and Greece. It has (the *S. maritima*) long been celebrated for its medicinal virtues; it is extremely bitter, and is esteemed as an expectorant, nauseant, and diuretic. The small hardy species are in every flower garden.

SCINCUS (SKINK, and also SCINCODÆ—the Skink family). The skinks form the eighth and last of the families into which Cuvier divides the saurian reptiles, and the general characters of the family are: the legs very short, the tongue not extensile, and the body and tail covered with imbricated scales, all of equal size. They all have more or less of a snake-like form, and some of them have two of the feet merely rudimental, or altogether wanting. The family comprises these genera. *Scincus*, *Seps*, *Bipes*, *Chalcides*, and *Chirotos* or *Bimans*. Some of them have acquired an interest in the history of quackery, but they rank rather low in the scale of animals.

SCINCUS. This is the typical genus of the family, and of course the one upon which the name is founded. The following are the generic characters: the feet four in number, and short; the body and tail of nearly the same length; no power of inflating the nape; no crest on the back; and no ruff or other appendage to the throat; the feet are rather well formed, and the hind ones are longer than the fore; the tail in general conical, and that and the body covered with scales, not very large, and regularly imbricated; the tongue is capable of but little extension; it is of a fleshy consistence, and cleft at the tip; the toes, which are longer on the hind feet than on the fore, are generally five in number, and have small claws; the head is small, generally of a quadrangular shape, and hardly to be distinguished from the neck at the occiput; both jaws are closely set with small teeth for their whole length, and, in addition to these, there are two rows on the palate; the

tympanum of the ear is seated more deep than in the lizards; and the anterior margin of the auditory opening is furnished with three or four teeth.

As is the case with all the reptiles, and with the *Sauria* more than any of the others, the various species of skinks are not well arranged, owing to their number, and the limited knowledge which we have of their manners. They are all natives of warm countries, and the typical species belongs to Africa; but there are some in the hot and dry parts of the south of Europe. From the character of the teeth, we naturally conclude that these reptiles feed upon insects; but very little is known of their manners, or their use in the economy of nature. As is often the case, however, the absence of an apparent use in nature led to the adopting of a fancied one. This was a medicinal one, and it is somewhat curious, though perhaps not unnatural, that such should have been the case—the causes of disease were unknown, and substances which had no other known utility were supposed to have medicinal virtues.

Common Skink (S. officinalis). This is the one which has been so much celebrated for its supposed medicinal virtues, though it is not the animal which the Greeks called by the same name, for that was the land crocodile of Egypt, which is a *Monitor*; but this is the one which has been so celebrated in more modern times, and which still maintains its character in some parts of the world to such an extent, that it forms a considerable article of export from Upper Egypt. The other is called *auran el pard* by the Arabs, and this one *el adda*. It is a small reptile, seldom exceeding six or seven inches in length, of a yellow colour, with some bands of black, and with the tail about one-third of the whole length. The scales with which it is covered have a metallic lustre, and, altogether, it is not an ugly creature. It is found in all the countries on the Upper Nile, and also in Arabia, inhabiting sandy places, where it burrows in the sand so quickly that one would imagine it crept into a hole ready made.

It would not be easy, and certainly it is not necessary, to enumerate all the imaginary virtues of the skink. They are older than the days of Pliny, and for hundreds of years it kept up its character as one of the most efficacious purifiers of the blood and renovators of the exhausted constitution. We believe that the dead bodies of these reptiles were boiled down into a kind of soup, a use to which, on account of their gelatinous nature, many reptiles which are now neglected might no doubt be turned. It is a curious fact, that the name "skink," and at least one part of the supposed virtue of it, by implication at least, are, or were till very lately, kept up by the country people in Scotland. Their *skink* was really beef soup, but it formed the stock dish at nuptial feasts, occasions upon which the virtues of the true skink were understood to be especially requisite.

Schneider's Skink (S. Schneideri) is one of the largest and most handsome of the genus. It is found in Egypt, and various other parts of the East. It has the tail round, and very small in the terminal part, and forming nearly two-thirds of the total length of the animal; the scales on the lower jaw, and also on the head, are longer than those on the other part; the upper part of the body is bright yellow, mottled with olive brown; the tail irregularly

mottled with black and yellow; a white band passes down each side; and the lower parts of the feet are white.

Paved Skink (S. pavementus). This species inhabits the same countries as the preceding, and resembles it in many particulars; but it is more slender, and has the tail longer. The upper parts are of a bright brown colour, and the under yellowish white, and there are four or five white lines extending from the upper part of the head to the middle of the tail. These lines masculate with each other, so as to give the upper part a spotted appearance.

There are some other species or varieties still, of the same parts of the world, which do not appear to differ from those that have been noticed in any thing but size and colour, and these can hardly be admitted as specific differences. There are also some in the south of France, in Barbary, in the south of Africa, and indeed in all the warm, dry, and sandy parts of the old continent, but there is nothing about them of any particular interest. We may remark, in passing, that one of the places of Europe upon which the smaller *Sauria* are most likely to be met with, is the sandy tract, below Montpellier, which lies between the plain of Languedoc and the sea.

There are several in Australia, and in the isles to the north and east, but they are not much known, or apparently of much interest. In the West India islands, too, there are reptiles which are at least very similar to the skinks of the old continent. Some of them are of larger dimensions; and they have not the same healing powers, at least in the estimation of the black population, as those of the east. There is one, called popularly the "galley-wasp," the bite of which is dreaded as being exceedingly poisonous, but the dread is wholly without foundation; for, instead of having a venomous bite which is speedily or instantly mortal, it does not appear to be capable of inflicting any bite at all. The West Indian ones, and indeed all that are found on the American continent or its islands, ought, in all probability, to be referred to another genus. They do not frequent the sand, but the holes of trees, and other places of concealment; and the one which is most dreaded by the negroes is partial to humid places. There are also some that have no teeth on the palate, and they probably ought to form a different genus. The habits of the family have been, however, wholly overlooked; and the only use of all that has been said of them in detail, is to enable the keepers of museums to arrange them in a particular way, and to say something about each, if that can be called use.

Seps. The name of this genus is supposed to be derived from the Greek verb "to corrupt;" but what they corrupt, or how they do it, no one has attempted to say. In many respects they resemble the skinks, but they make a nearer approach to the snakes. They are much more elongated and slender, and their feet are smaller, and farther apart. Indeed, they have the feet so very small and rudimental, that naturalists have often been puzzled what to do with them. In former times, when all the *Sauria* were called lizards, the seps were lizard-serpents, or serpent-lizards, according to the fancy of the party imposing the name. In so far as their habits are known, they probably resemble those snakes which have rudiments of extremities within the integuments more than they do the characteristic *Sauria*.

One of the usual modes of distinguishing them is by the number of the toes. Those which most nearly resemble the skinks have five toes on all the feet, and those on the hind feet of unequal length. Others, with the same number, but the toes of equal length, are the quadruped snakes of Linnæus. Some have four toes, but those with fewer than four are the most characteristic members of the genus, however, as they differ most from the skinks. We shall just notice two of them.

Three-toed Seps (S. tridactylus). This species has the feet and toes remarkably small, and the latter only three in number. The general colour is steel-blue, having two longitudinal bands of white, with blackish borders. It is by no means rare in many parts of the south of Europe, and also in the opposite part of the Mediterranean. Like all the rest of the family, it is a perfectly harmless creature, but it is, like them, regarded with very serious apprehensions by the country people. Some are of opinion that this seps is the "snake in the grass," the metaphorical allusion to which is so common. It is said to lurk in the herbage, and to occasion the most serious maladies to domestic animals, cattle especially, when they happen to swallow it. It does not appear that there is very much truth in this statement, which has very much the appearance of the stories of efts which are sometimes told with horror in the country. See the article SALAMANDER. The authorities say that this species is ovoviviparous, but it is doubtful.

One-toed Seps (S. monodactylus). If this is anything more than an imperfect specimen of the other, it is a very singular creature. The feet are described as being exceedingly short, with only one toe upon each, and apparently of very little use as organs of locomotion. The scales upon these are very small, and those on the body and the tail are marked with a sort of elevated crests. The specimens that have been described are from Southern Africa.

BIPES. These do not differ from seps in almost any other respect than that of having only two feet, and thus making a little nearer approximation to the snakes. The anterior extremities consist of hardly any more than a blade-bone, which is of course concealed under the integuments; the hind feet are also but little developed, and in some they appear to terminate in scaly plates, though, when examined, the usual bones are partially found, only there are no phalanges to the toes. They are found in New Holland, in Southern Africa, and in South America. They are perfectly harmless creatures, living in mud and rubbish, and very little is known of their habits.

CHALCIDES. The distinguishing characters of this genus are: the length of the body, as compared with its thickness, the smallness of the feet, and the great distance between the fore ones and the hind. They have very much the aspect of little serpents, but their scales are differently arranged from these, and even from the more typical members of the present family. Instead of being imbricated, they are of a rectangular shape, and so ranged as to form rows across, in the same manner as the scales on the tails of the true lizards. They also, in this respect, bear some resemblance to the *Amphisbæna* among snakes. This, in fact, is nearly the limit of the saurian type; and one feels not a little puzzled how to refer from these animals to others, so as to preserve anything like a

gradation. There are many species of these most harmless little creatures in the warm countries, but almost the only distinctions between one and another are the numbers of toes on the feet.

C. tetradactylus has, of course, four toes on the feet, but the feet are so exceedingly short, that they are hardly of any use to the animal in walking, which thus creeps on the belly very much in the manner of a snake, though it has not equal power in the spine to help it onward in its march. It is only about six inches in length; indeed, the whole of the genus are very small animals. They swarm in many of the warmer parts of the south of Spain, especially in the beautiful valley of Andalusia. Others are mentioned with three toes on the feet, and others still with only one; but it is highly probable that the latter has been confounded with the one-toed seps of Southern Africa, from which country the one-toed specimens supposed to be referable to this genus have also come. Some of the East Indian species have four toes tolerably well made out upon all of the feet; and others, in tropical America, have these organs so little developed, that it is not easy even to count them.

CHIROTES, or BIMANA. These have the character of bipes in so far reversed, that they are without the hind feet, while that genus is without the fore ones. Only one species is known, found on the table land of Mexico, which, as it is peculiar in its physical character, is peculiar in many of its productions, and especially so in its reptiles.

Bimana canaliculata is about eight or ten inches in length, and as thick as the little finger. It is flesh-coloured, and marked with about twenty-two half rings over the back, and as many on the belly, which meet each other alternately on the sides; it is on this account that it is called canaliculated or channeled, and, from the same markings, and also the colour, it is called *Lacerta lumbricoides*, the worm-like lizard; but it is not a lizard, neither is it in any respect like a worm. It has true fore feet, which are very well made out in their bones; they have blade-bones, clavicles, and a small sternum; and they end in four toes, and a rudiment of a fifth. In this part of its skeleton, therefore, it is organised like a quadruped, but in all the rest it more resembles the footless reptiles. Its tongue is but little extensile, and cleft at the tip, and ending in two horny points; its eyes are very small; and the tympanum of the ear is so much concealed by the skin, as not to be visible on the outside. There are two rows of pores on the under part in advance of the vent. The lungs make a nearer approach to those of the serpents than those of any others of the *Sauria*. They consist of one principal lobe, and of another which is very small and rudimental. This may, in fact, be considered as the last of the saurian reptiles, at least in so far as structure is concerned, for we know very little of its habits. That it feeds upon insects is very well understood, but the mode in which it gets at them is hardly known; and we have no knowledge whatever of the mode of its reproduction.

SCIRPUS (Dr. Brown). A genus of hardy bog plants known in Britain by the name of club-rush. The plants belong to *Cyperaceæ*. The *S. tuberosus* is the water-chestnut of the Chinese and is cultivated in that country. The roots of *S. maritima* are esculent, and they have been ground and used as flour

in times of scarcity. Some of the other species are used for chair and mat making.

SCITAMINEÆ. A natural order of plants, containing eleven genera and one hundred and twenty-six species. These last are mostly natives of the warmer parts of the world, and are stemmed or stemless herbs with long broad leaves, and bearing white, yellow, or red flowers, often of great beauty and fragrance. They are often large herbs, and even tree-like plants, with perennial, tuberous, or fasciculated fibrous roots. The stems are mostly round and simple, the axis being occasionally abortive; the leaves alternate, vaginant, and wing-nerved. The flowers united; the perianth superior, of six pieces, and irregular; the three outer ones like sepals, and the inner like petals. The stamens six, one or more often becoming like petals, and barren; the anthers one or two-celled; the pollen powdery; the germen inferior, three-celled or one-celled. Seeds many, style simple; stigma simple, or three-lobed; and the fruit capsular. The genera included in this order are, *Globba*, *Mantisia*, *Curcuma*, *Roscoeæ*, *Kæmpferia*, *Zingiber*, *Amonum*, *Costus*, *Hellenia*, *Alpinia*, *Hedychium*.

SCOLIIDÆ (Leach). A family of fossorial hymenopterous insects, having the collar either arch-shaped and extending to the base of the fore wings, or transversely square, legs short, thick, and armed with many spines, with the thighs curved near the tips, the antennæ shorter than the head and thorax in the females, but longer and straight in the males. These insects are for the most part inhabitants of tropical or hot countries, and some of them attain a very large size, being amongst the most bulky of the *Hymenoptera*. They are generally found in sandy districts, and the structure of the legs clearly indicates them to be fossorial. The genera are, *Tiphia*, *Myxine*, *Meria*, and *Scolia*; the first only being an inhabitant of this country. The genus *Tengyra*, hitherto placed in this family, has been ascertained to be the male of *Methoca*, one of the *Mutillidæ*.

SCOLOPENDRA (Linnæus). A genus of apterous insects, consisting of the species generally called *Centipedes*. See the articles *CHILOPODA* and *CENTIPEDÆ*.

SCOLYMUS (Linnæus). A genus of annual and perennial herbs, natives of Barbary and the south of Europe, called in English lists the golden thistle. Of course the genus belongs to *Compositæ*.

SCOLYTUS (Geoffroy; *Eccortogaster*, Herbst). A genus of small but very destructive coleopterous insects, belonging to the family *Bostrichidæ*, or more properly *Scolytidæ*, having the antennæ terminated by a large flat club commencing at the ninth joint, the abdomen beneath obliquely and abruptly truncate, the tibiæ terminated by a recurved spine, &c. There are several species of this genus of which the characters are not sufficiently determined, neither does it appear, from the recent memoir of Dr. Erichson, that the specific name *Destructor*, usually given in this country to the elm-destroying species, has been correctly applied. Without entering into the question of these specific names, we shall confine our subsequent observations to the insect above mentioned, and which, from the devastation which at the present time it is committing upon the elms in the public parks, gardens and promenades, both in this country and in France, may be considered as a public nuisance. This insect is generally almost or quite one-fourth of an inch in length, of a black colour and shining, with

the antennæ and tarsi reddish, and the elytra punctate-striate. It has been well figured by Mr. Curtis in the first volume of his *British Entomology*.

There has long been considerable discussion as to whether this insect attacked and destroyed trees which were in a healthy state, although it was admitted on all hands that they never attack dead trees. In the year 1825 a fine avenue of elms was destroyed in Camberwell Grove, which gave rise to a chancery suit between the inhabitants and the proprietors of the gas works, from which the neighbourhood was supplied with gas, which was supposed to be the cause of the mischief. On this occasion the general conclusion of persons employed to examine the trees was, that other causes either than the gas or the insects induced the decay of the trees; but it was not until the last year or two that the natural history of the insect, which could alone lead to a satisfactory view of the subject, has been entomologically studied by Mr. Spence and M. Audouin of Paris, the latter of whom has published a notice on the subject in the *Annales de la Société Entomologique de France*, for the past year (1836). The observations of Mr. Spence have been communicated to the Entomological Society of London, and the result thereof to Mr. Loudon, who has embodied them in the article *Ulmus* in his very valuable work, the *Arboretum Britannicum*, for the last month; and, from the importance of the subject, we trust that we shall be excused for communicating the following practical extract from that work. "It is quite true, as Mr. Denson maintains, that the female *scolyti* never deposit their eggs in trees perfectly healthy, but it is equally true that both they and the males pierce young and healthy trees for the sake of eating the inner bark, which constitutes their food; and that the numerous holes which they thus cause, partly from the loss of sap which exudes from them, and partly from the effect of rain which lodges in them, in a few years bring the trees in which they occur into that incipient state of ill health, in which the female selects them for laying her eggs just as in trees beginning to decay naturally, and thus *healthy trees are effectually destroyed* by the combined operations, first and last, of the *Scolyti* of both sexes, though not in consequence of the sole deposition of the eggs of the female." This explanation, first detected by M. Audouin, and subsequently confirmed in numerous instances by Mr. Spence, in the boulevards of many of the towns of the north of France, from Dunkirk to St. Lô and Granville, satisfactorily reconciles the conflicting opinions of previous observers, and proves that hundreds of young trees may be brought into an incipient state of decay by the *Scolyti* without containing a single egg.

"It is scarcely possible," continues Mr. Loudon, "to overvalue in an economical point of view the importance of M. Audouin's discovery, which if it had been formerly known and acted upon might have saved the greater part of the fine elms in the promenades of many of the principal cities in the north of Europe, which have fallen victims to the ravages of *Scolytus destructor*, as well as 50,000 young oaks in the Bois de Vincennes, near Paris, which it has been recently necessary to cut down in consequence of the attacks of another insect of the same tribe (*S. pygmaeus*). The practical directions to which it leads, in all cases where there is reason to suspect the presence of *Scolyti*, are very simple, and may be briefly expressed as follows.

"1. The first thing to be done is to pare away the exterior rough bark with a cooper's spokeshave, or other convenient tool; this admits of a distinct inspection of the actual state of the trees, which, if there is no trace in the inner bark either of small holes in old trees, or of those superficial furrows which the *Scolyti* make for food in young trees (and which may be distinguished from the natural crevices in the bark by their dark-coloured and dead margins), may be pronounced to be in a sound and healthy state, and requiring no further attention.

"2. If the inner bark exhibits either of the appearances above mentioned, the next thing is to ascertain whether the female has already deposited her eggs in it; and if it contains the larvæ of the *Scolyti*, to know which it is necessary to cut away portions here and there of the bark down to the actual wood and examine them; and if the existence of the larvæ be proved, the trees should be cut down and their bark peeled off, and every fragment of it carefully burnt.

"3. Those trees which, though pierced with exterior superficial holes or furrows, have no larvæ in them, are such as have been attacked by the *Scolyti* for food only; and if they be carefully brushed over with coal tar, the smell of which is highly offensive to the perfect *Scolyti*, there is every probability that they will be secure from the future attacks of the females; and that the repetition of the same process in the spring for a year or two would enable them to resume their vigour and to become healthy trees; for the future fate of which, if at the same time the entire removal of all the trees actually diseased has been attended to, there would be no need of apprehension. It is in this way, as we are informed by Mr. Spence, that a great number of the young elm trees on the boulevards of Brussels, brought into an incipient state of debility by the attacks of the *Scolyti* for food, but not yet attacked by the females, were treated on the spring of 1836 with every prospect of a successful result, though of course some years must elapse before any absolute deductions can be drawn from the experiment."

In conclusion, we cannot but regret that the assistance of some competent person was not required by the Commissioners of Woods and Forests, previous to the wholesale and indiscriminate felling of the trees in Kensington Gardens, the ornament of the metropolis, which it will require so many years to replace, where sound and unsound trees of other kinds have been cut down to the ground. Let us hope, now that the preceding observations have led the way to a more precise acquaintance with the subject, that the axe will be laid more sparingly to the trees which still remain.

SCOMBEROIDÆ—the Mackarel family. The seventh in order of the fifteen families into which Cuvier arranges the *Acanthopterygii*, or spinous-finned fishes, and one which in the number of its genera and its species, the countless myriads of its individual members, the vast numbers of them that are caught, and the excellent qualities of the flesh of very many, may be reckoned among the most interesting and valuable of all the inhabitants of the ocean. They are all fishes of great power in the water, swimming with incredible energy, generally at no great depth, and often appearing at the very surface, where many of them display a brilliance, variety, and change of colour, which defy all powers of description. Inhabiting thus near the surface, they are fishes which

breathe much more than those that live at a greater depth, and thus they die more speedily when taken out of their native element than those fishes which have a slower action of the system, and inhabit further down. It is a pretty general law too, that fishes (at least bony fishes) which have rapid action and breathe much, cannot be kept so long after they are taken out of the water, as those in which the action is more moderate. The mackarel family agree with the law in this, and none does it more than the common mackarel. No fish, obtainable in any thing like the same quantity, is better than mackarel when perfectly fresh, but there are few that sooner become tainted and unwholesome.

No sea that can be named is without one or other of the members of this numerous family, and there are seas in which a great variety of them are to be met with. But even the outline of their history would fill volumes, and therefore we can do nothing more than indicate the leading genera, and mention one or two of the species which are most interesting to British readers. The family contains in all fifteen leading genera; but in many of these the species differ so much from each other, or are so numerous, that Cuvier, who had no disposition to make any wanton increase of divisions in any part of the system, found it necessary to subdivide them into more than thirty subordinate genera, in addition to these leading ones.

The general characters of the family are: the surface of the body smooth, the scales small, the muscles of the posterior part of the body, and the caudal fin especially, very powerful. There is one part of their muscular structure which is worthy of attention, as showing the peculiar organisation of a fish which is formed for getting rapidly through the water by muscular action alone, without much assistance from the resistance of raised posterior edges to the scales. The flakes, as they are vulgarly called, are thicker; that is, they measure more in the direction of the length of the body than they do in fishes that have large scales, and especially than those which inhabit lower down and have less powerful action in the water. This admits of a greater length of the individual muscular fibre; and thus the contraction and bend resulting from it are more rapid and more extended than if the fibres were shorter and there were a greater number of them in the same length of the body of the fish. Some members of the family are without any air-bladder, and others have one, which is one of the many proofs that this organ, whatever may be its use, is not absolutely indispensable at any particular depth in the water, or for any particular rate of swimming. We shall now barely enumerate the genera.

SCOMBER (Mackarel properly so called). This, which is the typical genus of the family, is subdivided into eight; the first of which is,

Scomber (the common mackarel). This is a fish which every body knows; and in the elegance of its form, and the beauty of its colours, it is equalled by few fishes. It of course partakes of the distinguishing characters of the genus, the most obvious of which are, the form of the second dorsal fin and the anal; these have some of their rays nearest the tail detached and forming a series of processes which get the name of false-fins. The characters more peculiarly descriptive of the mackarel itself are: the body spindle-shaped, or thick at the middle, and tapering to both

extremities, but especially to the tail, and being what may be regarded as the model of a swift fish, just as the form of a falcon is the model of a swift bird. There are no scales on the ventral fins; the two dorsal fins far apart, the anal under the second one, and the false fins or filets extending from both to the bases of the caudal, or nearly so. The tail is a little forked, and the two lobes of the fin stand diverging from each other, and are much pointed. The fin is not very large, but its form remarkably fine; and though the body tapers toward its base, the thickness from side to side gives it much muscular strength even there. It is indeed quite a study for such as are fond of the very beautiful and instructive science of animal mechanics; and in it, as in other cases, we find that the maximum of energy depends upon form, not upon mere mass. To describe the colours, or any of the other particulars, would be superfluous; the adaptation of the mackerel to very rapid motion in the water is the part of its appearance which contains the valuable lesson.

When the old notion of the migration of fishes over long distances from one part of the world to another was in fashion, the mackerel was included in the catalogue of migratory fishes. It was not then considered that the migrations of animals from latitude to latitude were produced by the action of the seasons upon them, and that, as there is very little seasonal action in the sea, there can be no need for such migration on the part of the fishes. The mackerel is, upon ordinary occasions, a discursive inhabitant of the deep waters, where the bottom is too remote from the action of the sun and air for being fit for hatching the roe of a fish. Therefore, for the very same reason that the salmon ascends the rivers, and herrings and many other fishes come toward the shores at certain times of the year, the mackerel comes into water more shallow than that in which it finds its food at other times. Then, as we cannot suppose that the water over the deep where the bottom is barren of life can furnish such a supply of food as over the shallows where the bottom is fertile, the mackerel and other fishes, which come periodically toward the shores in shoals, must live much more dispersedly in their deep sea haunts. There is something very beautiful in this even in so far as use to man is concerned. Man could not fish the breadth and depth of the great ocean for those fishes which find their food there, and thus a very large portion of the waters would be a waste to him, in spite of the utmost exertions of his industry. But the fulfilment of the law of nature brings these fishes toward the shores, one at one season and another at another; and thus the fishes are, as it were, constrained by the law of nature to fetch the treasures of the deep to those places where man can derive advantage from them; and the great vigour of action which fits them for their labours in the ocean, enables them to find food upon the more fertile because more shallow places, in shoals far greater than fishes of less energy of action could exist.

The time at which the mackerel fishing commences, or, at all events, is most productive on the different parts of the British coasts, shows pretty clearly whence the fish come, and of course that is the place to which they retire when they take their departure. The sea on the east coast is not deep enough for them at ordinary times, and that on the north is too cold. The Atlantic is therefore the pasture to which they

retire when the spawning upon the coast is over. When they make their appearance on the shores, it is at first on the south-west; and they appear there in the greatest number, and the fishing continues longest. From the south-west of Cornwall to the northern isles, the time which they take to travel is nearly five months, and comparatively few reach the latter locality. Their appearance is not, however, strictly geographical; for the character of the bottom in the offing appears to have a considerable influence upon them. The water over the sandy shallows of course gets first warm, and this tends to mature the spawn, and consequently the fish not only first approach the land in such places, but are earlier in the finest condition.

There is another circumstance worthy of notice in the seasonal economy of these fishes. At the time when they come to the shores, the fry of those fishes which spawn in the winter or early in the spring, is very abundant, literally swarming to a thousand, or, probably, many thousand times the number which could come to maturity with a due balance of the system; and then the surplus goes to feed the mackerel, and the other discursive fishes that come from the deep water during the summer. From the difference of time between their appearance on the southern and the northern coasts of Britain, it is of course impossible to lay down any precise time by the calendar for their spawning, though perhaps about midsummer may be the average time for the British shores. They are not the most prolific of all the fishes certainly, but still they are very prolific, the produce of a single roe amounting to about half a million; and it will be borne in mind that, in the case of a fish, the bringing of the eggs to maturity is all the labour that devolves on the parent, the hatching of the eggs being produced by the elements, and that generally, if not always, after the parent fishes have retired to other parts of the water. As on all parts of the coast which they frequent, they spawn in the very warmest part of the season, the spawn is very soon hatched; and in about the period of two months the fry are understood to grow to the length of four inches or thereabouts, and they soon after retire from the land. Mr. Yarrell is of opinion that one principal article of the food of mackerel on the coasts of the channel is the fry of the sprat; and it is by no means unlikely that this fry, and also that of the pilchard and the herring, are eaten by them in great numbers; but in the case of all these fishes, there is enough and to spare.

Mackerel, as being in all probability the most seaward and discursive fishes which come regularly and in vast numbers to the shores of Britain, and afford a most valuable fishery, offer many inducements for going into a general inquiry respecting the relative dependence of the sea, and of the fishes of different places, depths and distances from the land, upon each other; but the subject, though one of great interest, and not only worthy of, but imperatively demanding far more attention than it has hitherto received, is much too extended for our limits, and indeed for being taken up with advantage as a part of the discussion of any other subject. We must therefore confine ourselves to a few notices of the fishing, the substance of which we shall take from Mr. Yarrell, as the latest and best authority upon the subject; and as drawn from the personal observation of others in all cases which his own observation did not reach, and where he himself has not stated the fact to be otherwise.

The following extract will show the numbers, and the fluctuation of the prices. "In May, 1807, the first Brighton boat-load of mackerel sold at Billingsgate for forty guineas per hundred, seven shillings each, reckoning six score to the hundred, the highest price ever known at the market. The next boat-load produced but thirteen guineas a hundred." Then for the contrast:—"Mackerel were so very plentiful at Donn in 1808, that they were sold sixty for a shilling," one four hundred and twentieth part of the price of the first boat-load at Billingsgate just the year before. "At Brighton, in June of the same year, the shoal of mackerel was so great, and one of the boats had the meshes of her nets so completely occupied by them, that it was impossible to drag them in; the fish and nets, therefore, in the end, sunk together; the fishermen thereby sustaining a loss of nearly 60%, exclusive of what the cargo, could it have been got into the boat, would have produced. The success of the fishery in 1821 was beyond all precedent. The value of the catch of sixteen boats off Lowestoffe on the 30th of June, amounted to 5,252*l.*; and it is supposed that there was no less an amount than 14,000*l.* altogether realised by the owners and men concerned in the fishing on the Suffolk coast. In March, 1833, on a Sunday, from Hastings, boats brought on shore ten thousand eight hundred mackerel; and the next day, two boats brought seven thousand fish."—Yarrell's *British Fishes*, vol. i., p. 125, 126.

The mode of capturing fish, which sometimes fetch so very exorbitant a price, and are at other times caught in such numbers, and sold so cheap, is a matter of considerable interest. The method of capturing them in the wholesale way, and out at sea, is by means of drift-nets, that is, nets which are allowed to drive with the current of the water, in the same way as is done in the capture of herrings on the grand scale. They are also both caught in the same way in the net, that is, in the meshes, and not by having the net drawn round them, so that the individual mackerel are caught each in a mesh, in the same way as herrings are, and not by enclosing the shoal as is done in the case of pilchards. The net is twenty feet in depth and six times as much in length, well buoyed up with floats against its own weight and that of the fish, that it may entangle, but it has no weights at the bottom. A number of these nets are often tied together, and the boat remains at the end of the drift-rope, or head-rope of the net, to serve as a sort of anchor. They are usually shot in the evening, and drawn once, and shot again during the night, or left undisturbed till the morning, according to circumstances; the management of a fishing ground being a matter of local experience, which none ever do so well as those who have been regularly trained to it. When the net is drawn, a capstan is ready in the boat for the purpose of hauling it home, and the fish are either rowed to port in the boat, or the boat remains on the station, and another vessel removes the fish, according to circumstances. This is the method of fishing on those parts of the mackerel grounds which are most distant from the land. Nearer the shore a kind of seine is employed with smaller meshes than those of the draught net, and the net is worked by the crews of two boats, whose object it is to surround the fish, and secure them in the bight of the net. Mackerel are also taken by hook, and this indeed is the usual mode upon those parts of the coast where mackerel are not very plenty, and

where, in consequence, the fishing is not carried on upon a large scale, or very systematically. Mackerel are so very voracious, that the kind of bait used for them is not a matter of much consequence. A slip of mackerel itself, with the shining skin on, a bit of red cloth, any thing, in short, that makes a conspicuous appearance in the water will do, and it is all the better if the fishing-boat is kept in rapid motion, and that the surface of the water or the state of the atmosphere is such as not to admit too much light. A "mackerel breeze," which just breaks the surface into ripple without any long waves, is understood to be the most advantageous, and if it is accompanied by a "mackerel sky;" that is, an atmosphere dappled with clouds something resembling the colours of a mackerel, so much the better. Under these circumstances, the mackerel seldom fail in taking the bait, and if they take it, they are sure to be caught: for, whatever the bait may be, they take it so greedily, that they are sure to be fastened on the hook beyond all possibility of extricating themselves. It is generally necessary to use a weight as a sinker on the line, or rather on a sort of head line to which that carrying the hook and bait is attached, and floats at some distance in rear of the weight. We may remark in passing, as rather a curious instance of uniformity of words among fishers, that the shoal of mackerel, herrings, and all other fishes which come to the shores in great numbers for their seasonal purposes, is pronounced as if it were written "school," both in Cornwall and in Caithness.

The muzzle of the mackerel is very much pointed; the lower jaw is longer than the upper, and the teeth are in a single row in each jaw, conical in their shape, but having their points inclined toward the pharynx. The whole structure and curvature of the mouth show that these fishes take their food only as it swims in the free waters, and never on the banks. The pectoral and ventral fins are both in advance of the dorsal, the vent is opposite the beginning of the second dorsal; and the finlets behind both the second dorsal and the anal are few in number. The grand colour of the back is rich green, mottled with blue, and with transverse bars of dusky white, which are generally said to be straight in the males, and wavy in the females. The males have, also, the gill-covers longer and the body thinner in proportion to its length than the females; but the proportions of the parts of the body to each other are much the same in both. The colours of the lower sides and under part are not very easily described, and they speedily change after the fish is exposed to the air. Silvery, with clouds and reflections of golden bronze, of many varying shades, may be described as the general colour of those parts.

Scomber colius (The Spanish mackerel) is a rare fish on the British coasts as compared with the common mackerel. It is a thicker fish than the common mackerel, with the eyes larger and the gape wider, but the teeth not so large. The under part is beautifully mottled with golden and silvery metallic lustres interspersed with yellow spots. It is by no means rare in the seas of the south of Europe, and great quantities are taken on the coasts of the south of France.

Scomber lar (the lar mackerel) is a native of the Pacific, and fished for by the inhabitants of several of the islands which spot that ocean, especially by those of New Ireland. It is larger than the mackerel of the European seas, and an exceedingly beautiful fish in its colours. The upper parts are mottled with

red spots and lines of golden-yellow upon a rich green ground; and the under parts are silvery with a fine rosy tint. In the season vast numbers of them approach the shores.

TUNNUS—Tunny. This, though sometimes caught on the shores of Britain, is a rare fish with us; but it is very plentiful in the Mediterranean, and has been known and celebrated from the remotest period of antiquity at which we have any mention of fish by particular names. It has many qualities to recommend it, being very handsome, very large in size, and in much estimation as food. The characters are: the body resembling that of the mackerel, but thicker across in proportion to the length; the fore part of the body having a sort of mantle composed of numerous scales; the first dorsal extending nearly to the second, and becoming much lower toward the posterior part; the anal fin in rear of the second dorsal, and both of them divided into numerous filets toward the tail; and the sides of the tail with a distinct keel.

The tunny is altogether a much thicker and stouter fish than the mackerel. Pennant saw one, which had followed the herrings into Loch Fyne, killed at Inverary, the weight of which was four hundred and sixty pounds; and specimens larger than this have been mentioned. The length of the one in question was seven feet ten inches, which were very large dimensions for a fish of the active and discursive habits of the tunny. But the tunny is, properly speaking, an inhabitant of warmer seas than those of Britain, and of course makes its appearance there only as a stray, diverted from its proper track by the prey of which it is in chase and not in quest of spawning ground, as is the case with the mackerel.

During the greater part of the year the tunnies are discursive through the ocean, but in the summer they resort to the shores in vast shoals; and all along the north-coast of the Mediterranean, and in the island of Sicily, the tunny fishery is carried on, with much activity, and the flesh of the tunny, both in the recent state and salted, forms a considerable part of the food of many of the people, and no small part of the wealth of those who reside on the coasts. The months of May and June are the great ones for this fishery, and they are looked forward to with much expectation.

There are two modes of fishing, the one by temporary nets shot from the fishing-boats, and the other by fixed ones. Confederacy is necessary for the working of both, as the fishes are very timid when they approach the land. They range along the shore at no very great distance, so that the place and direction of the shoal can be seen by sentinels placed on the heights. The boats then advance uniting their nets, and forcing the fish into the shallow water, from which they are taken by means of a large tunnel net. The large ones are, however, always killed in the net; but the small ones are carried on shore. The fixed nets are placed parallel to the shore, at such a distance as that the fish shall come between. There are cross nets, which have small openings, the passing of which gradually brings the fish into close array, until they are in the last enclosure of the net, which is emphatically called the "chamber of death." In this they are secured; and it has a net at the bottom, the raising of which brings the whole shoal to the surface, where they are despatched, by beating them on the head with poles. When taken in such quantities, the greater part are cut in pieces and salted, or part

are often pickled much in the same way as we pickle salmon.

When raw the flesh of the tunny has a colour nearly as red as that of beef; but it becomes paler when boiled. The flavour is much famed, but the consistency is much harder than accords with our notions of fish of the first quality, being more so than even that of the sturgeon, though the tunny is the better flavoured fish of the two. It is dressed in a great variety of ways.

The spawn is deposited about the same time of the year as that of the mackerel. It is speedily hatched, and by about October the fry, which are then nearly two pounds in weight, quit the shore for the deep water. The tunny has a family likeness to the mackerel, but it is shorter and thicker in proportion; the head is rather short, the gape not very wide, and the teeth small and in a single row, but exceedingly sharp. The inside of the mouth and the tongue are very dark-coloured, the first dorsal fin folds down into a sort of groove on the back, and there is a spine in advance of the second one. The upper part is dark blue, with the scales on the mantle lighter; the under part is greyish white, with silvery spots, which are produced up the sides; and the sides of the head are white. The first dorsal, the pectoral, and the ventral fins are black; the caudal fin is dusky, the second dorsal and the anal are flesh-coloured, with silvery reflections, and the filets are yellowish with black tips. The caudal fin has always fewer rays than that of the mackerel, and the number varies in different individuals. There is another tunny, still more southerly in its habitat than the tunny of the Mediterranean, which may be noticed, which is

The Bonito, or Striped Tunny (T. pelamys). This is, like its congener, a very roaming fish; and though it does not appear regularly in the British seas, or resort to the British shores to spawn, yet occasionally occurs as a stray, following and feeding upon the smaller fish. The shape is nearly the same as that of the tunny, but the size is smaller, the length rarely being more than two feet and a half. The colour of the upper part of this species is steel blue; the sides dusky; and the under part whitish, with three dusky stripes from the pectoral fin to the posterior part of the fish, parallel to each other and to the outline of the under part, and terminating backwards at the lateral line. The dorsal fins and the anal one are concave in their margins, and the filets are enlarged at the tops, so as almost to reach each other at the extremities, though their bases are at some distance apart. The lobes of the caudal fin are very long, and placed so nearly at right angles to the axis of the body, that the tail is but slightly concave in its posterior margin. The flesh, as is the case in all the fishes which are powerful swimmers near the surface in the wide seas, is very red and full of blood.

The bonito occurs in the Mediterranean; and there are, indeed, two species which get the name, the chief difference between which seems to be, that the teeth in the other one are much larger, and the sides are marked with dusky bars across. It is in the ocean that these fishes, and some of the other large members of the mackerel family reside. The flying fishes are the grand object of their pursuit; but they catch very indiscriminately at any thing that moves in the water; and thus they are often captured by the sailors, to whom they afford a very welcome and acceptable mess, though their flesh is dry, and not of

the very best flavour. The fishes are not very particular in their own eating. The only ground of selection appears to be what they can swallow, in preference to what they cannot; and it is even said that, in the absence of animal food, they will eat the seaweed which floats in the eddies of the ocean. The bonito is among the rarest of those fishes of the warm seas that occasionally straggle to our shores. There are a few more of the subordinate genera of the great genus mackerel, which resemble the tunnies in some particulars, and differ from them in others; but their habits are all nearly the same. We shall therefore proceed to notice another of the leading genera.

XIPHIAS (Swordfish). This is a fish of so much celebrity, that it has got a nominal place among the stars as a constellation; and certainly, numerous as are the inhabitants of the ocean, there are none of them more deserving of celebrity than the members of this genus. Cuvier divides them into four sub-genera; but our limits will not permit us to go into the details of these. Several of them abound in the Mediterranean, and a stray of at least one of this is occasionally found on the British shores, while numbers occur in the open sea, still further to the north. There are others which are more confined to the tropical seas; and they attain a very large size, and may fairly be designated terrible fishes, for bulk, armature, action, and every other attribute that can render a fish entitled to the name.

In their internal organisation, the extreme smallness of their scales, in the crests on the tail, and in the vast power of the caudal fin, these fishes have a considerable resemblance to the tunnies; but in other respects they are distinct. Their most remarkable character is the production of the upper jaw, in an instrument formed like the blade of a sword, with hard spiny tubercles on each side, and nearly half as long as the head the body and the tail taken together. This consists chiefly of a prolongation of the intermaxillaries and the vomer, supported by the ethmoides. It is the only weapon which these fishes have, for though they have some small teeth on the bones of the pharynx, they have none on either of the jaws, and they have no tongue properly so called. The produced jaw is, however, a truly formidable weapon, for they can not only plunge it to the hilt in the body of the very largest marine animal, but can drive it through the planking of a ship, and into the timbers, until it breaks in two with the violence of the concussion. When such an occurrence takes place, those on board the ship, even though of considerable burden, are said to feel a shock, similar in kind if not in degree to what is felt when a ship strikes against a rock. The gills of the sword-fishes are peculiar; they do not consist of fringes in the form of the teeth of a comb, as is usual among the bony fishes, but each consists of two large parallel laminae, with reticulated surfaces.

This peculiar form of the gills, which are so very important organs in the vital system, would lead us to suppose that there must be something in the habits of the fishes which renders this peculiarity of the breathing apparatus necessary; and when we come to examine the action of these fishes, we find that such is really the case. Mackerel themselves are swift in the water, and so are others of the family; but the sword-fishes dash along like thunderbolts in the water, and thus the impetus with which they de-

liver their weapon, is perhaps greater than that of any other animal. This extreme rapidity, and the rebound which must ensue when they strike against an animal or other substance of sufficient mass for offering resistance, would be serious to them if they had gills fringed in the usual manner; for the fringes would get entangled, the circulation would stop, and the fish would be strangled. The laminated gills are not exposed to this; and so, possessing them, the fishes can drive away with safety.

It is not, however, for their curious weapon, their size, and their speed only that these fishes are so celebrated; for the flesh of them is excellent, superior perhaps to that of the tunny, though, like the flesh of all the driving about fishes, we may suppose that it is dry when dressed in the same way that we are in the habit of dressing the flesh of the soft fishes. The sword-fishes also offer the surplus of their number readily to the use of man; that is to say, they come to the shores in obedience to the grand impulse of nature during the summer months, and they keep so near the surface and are so large, that they are easily seen. It does not appear that they shoal in any considerable number, and they are rather sturdy for net-fishing, unless it were conducted upon a scale of magnificence and expense, which could hardly be done by such people as the inhabitants of the shores to which these fishes resort in the spawning season; and when they are in the wide sea, of course any fishing for these or any other of the mackerel family is out of the question. We shall now mention the sub-genera, but confining the few details which we have to offer chiefly to the one which is found in the British seas.

These sub-genera are;—*Xiphias*, the sword-fishes properly so called, of which we shall afterwards say something more at length; *Tetrapturus*, so called from four projecting crests, two on each side of the base of the tail, and which has the snout formed like a dagger, and each of the ventral fins only a single little lobe without any articulation; *Makara*, which is known we believe from a single specimen only, is like the preceding in all respects, only it wants the rudimental ventral fins, but this may be merely accidental in the specimen on which the subdivision is founded, as it is known that the common sword-fish, the typical one of the genus, wears away the anal fin as it gets old, though that fin is complete when the fish is younger; and *Isteophorus*, which have the snout and the crests on the tail like the last, but the dorsal fin very high, and the ventrals long, slender, and each composed of two rings. The dorsal fin in these is said to catch the wind in the same manner as a sail, and thus to assist the fishes in their progress through the water. It may do this, and it appears to do it; and the fact that several members of the family can elevate and depress the dorsal fin at pleasure, shows that this fin has different uses upon different occasions. This is understood to be the sub-genus or section which contains the great sword-fishes of the tropical latitudes, in which latitudes they are very numerous in all the three oceans; but when we come to consider a genus of which the known habitat is the Atlantic, the Indian Ocean, or the Pacific, the field is too wide for permitting us to speak with confidence as to the details. It is generally supposed, however, that these are the ones that drive against ships with so much force, and leave part of their swords in the timber as proofs of the fact.

Common Sword-fish, (Xiphias gladius). This is the one which there is the greatest probability, (though not a very great one,) of meeting with on the British coasts; and it happens also to be the typical species, so that on both these accounts it is the one of which it is desirable to give a few details.

The generic characters are; the head triangular in profile, but drawn out into the lengthened sword of the upper jaw in the manner that has been already described; the thickest part of the body near the setting on of the head; one dorsal fin rising from the nape and continued for a great part of the length of the body, the outline of the anterior part concave, and that of the posterior part convex; no ventral fins; the tail with strong keels, and the rays of the lobes greatly produced; the gape not very deep, the lower jaw pointed; the jaws without teeth, and the sword-shaped portion of the upper jaw very long, and strongly supported at its base; the body covered with very minute scales.

The common sword-fish is very abundant in the Mediterranean, where it has attracted much notice from the most early times. As is the case with all the family, it is discursive, excepting at those times when it approaches the shores for the purpose of spawning; and although it would not, perhaps, be quite correct to apply the epithet "timid" to a fish whose armature enables it to defy all its fellow inhabitants of the deep, yet it is at all events a cautious fish. Though longest and best known to naturalists as a native of the Mediterranean, it often roams into the ocean, seldom, as it is said, upon the parallel, but either northward or southward, of the strait of Gibraltar. That this should be the direction which it takes in its wanderings, we might be prepared to expect, for in the sea, especially, we know of no animal that migrates longitudinally upon the parallel, neither do we know of any cause or inducement that they could have so to migrate; because in the sea, there is no change of climate upon the parallel, and nothing for which a fish could migrate, except toward the shore to spawn, and from it after that operation is over. Even in this case there appears always to be a movement in latitude, and in the case of the summer spawning fishes, this movement appears, in our hemisphere, to be chiefly toward the north. We have already pointed this out in the case of the common mackerel, and we believe it will be found that in the Mediterranean, the whole family resort much more to the northern shores than to the southern ones for the purpose of spawning. There are physical reasons why this should be the case, but our limits will not allow a full examination of them, and a partial one would be of little use.

From the time of the very earliest authentic notice of British fishes, the sword-fish has been included in the number, though only as an occasional straggler; but out in the ocean it is much more common, and ranges further to the north. Indeed, as an occasional fish on the coasts, it has oftener appeared on the Scottish than the English; and in latitudes still higher it is more common both in the open ocean and in the Baltic.

Its antipathy to the whale has been the subject of much description, and though there seems to be no reason for doubting the fact, the reason is by no means so apparent. That a sword-fish could "swallow a whale," is of course out of the question, and as little could it bite, as it has got no teeth in the jaws; and

then though it may use the sword in "cutting up" large animals into mouthable morsels, the fact of its actually doing so has not been to any extent proved. We quote an account of the mode of attack on the whale by the sword-fish, and its auxiliary, the thrasher, given by Captain Crow, as having been witnessed from a vessel on its passage to the Baltic. "One morning," says he, "during a calm, when near the Hebrides, all hands were called up at three A.M., to witness a battle between several of the fish called thrashers, or fan-sharks, (*Carcharias vulpes*), and some sword-fish on the one side, and an enormous whale on the other. It was in the middle of summer, and the weather being clear and the fish close to the vessel, we had a fine opportunity of witnessing the contest. As soon as the whale's back appeared above the water, the thrashers springing several yards into the air, descended with great violence upon the object of their rancour, and inflicted on him the most severe slaps with their long tails, the sound of which resembled the reports of muskets fired at a distance. The sword-fish, in their turn, attacked the distressed whale, stabbing him below; and thus beset on all sides, and wounded, when the poor creature appeared, the water around him was deluged with blood. In this manner they continued tormenting and wounding him, until we lost sight of him, and, I have no doubt they in the end completed his destruction."

Such is the account given by Captain Crow of what he saw, and of course we do not mean to call the seeing of it in question, because we think every man has a right to see all that he can see, and as much more as possible. We almost regret, however, that it has been quoted by Mr. Yarrell, because those who cannot draw distinguishing lines, will be apt to fancy that he saw it, and we are quite sure that Mr. Yarrell has too much good sense for seeing any such thing. In the first place we would ask, from what fulcrum, or *point-d'appui*, did the sharks deliver the blows with their tails, so as to give reports like muskets, when they descended on the whale? If the body of the shark was supported upon that of the whale, then the tail might strike; but if the shark made its stroke from the air, falling from the height of only a few yards, we know of no momentum that it could have, beyond that of its body, as a certain weight of matter falling from this trifling height, and that could not be very great. Then there is another trifling question connected with the conduct of the sharks; what part of their backs served as the fulcrum from which they leaped out of the water? We of course do not mean to deny this statement, neither do we mean to deny that the shark in question can give double blows with the long lobe of its one-sided tail. All that we doubt is, that the leaping of the shark some yards into the air could much help the violence of its blows, because the force of a blow must always depend on the power of resistance in that from which it is delivered.

But supposing all that is said of the thrashers to have been seen, there is more of doubtful matter in this most marvellous infliction upon the poor whale. The sword fishes made "their gashes" upon the *under* side of the enormous brute, (we presume we may say "brute" as the whale is mammalia, not fish?) and the question to which we desiderate an answer is this: How were the attacks of these fishes upon the *under* side of the whale seen? A whale of

any dimensions, and especially "an enormous whale," is not the most transparent of all media; and besides there are certain optical reasons why "ordinary" light will not reveal what goes on under water, to say nothing about under a whale, even at a very moderate distance. We still do not mean to deny that all which is stated was seen; because some men see "visions," but they very generally have another gift along with this, they "dream dreams," and it may be that herein lies the whole explication of the matter, and our philosophy may lie on the shelf. The result of the whole is, that the account given by Captain Crow must be true, and yet we cannot believe it, though discounting it; there is still enough of matter for marvel about the sword-fish. We would even go a little farther than this, and ask *cui bono?* in the case of the sword-fish attacking the whale. It is possible that there may be here some reasoning from the analogy of the sword among men. That sword, it must be admitted, conduces to no useful purpose—does not go to promote the real advantage of the human race one single iota; for all the swords that ever were drawn never contributed so much to the well-being of the world as the growth of one single potato. This may be all very well with human beings, and must of course be very well, inasmuch as the most sainted and saintly of monarchs have generally been the most ultra patronisers of the sword; but we are yet to learn that fishes have even the smallest chance of canonization on the same grounds, which may be very bad taste on the part of the said fishes, but not the less natural upon that account.

Whoever chooses to examine the figure of the sword-fish, must at once see that all its powers of motion are concentrated in the caudal fin, and that the chief use of the very high dorsal must be that of keeping the body of the fish steady to the line of its motion.

The prolonged snout forms an excellent cut-water, and the regular increase of the head gives that part nearly the form of the "solid of least resistance" in passing through water. In the anterior part of the dorsal fin the rays are stout; and it stands on the thickest part of the fish, while toward the rear the rays are smaller and closer together, so that the fin is much more flexible. The absence of abdominal fins is against the fact of the fish having much motion in ascent or descent, and it seems doubtful whether the fish can use its weapon very vigorously or effectively at close quarters; for an instrument of such dimensions would require to get a momentum, the acquiring of which must be had by a considerable "run" on the part of the fish. This also is against the notion of the wanton attacks on the whale, though still we do not mean to deny that these attacks are made. The pectoral fins are long, and placed lower down on the sides than they are in fishes which have abdominal fins. The anal fin is

continuous in the young fish, but in the old ones the middle part of it, which has the membrane very thin and tender, is worn away, so that the portion near the tail is a mere finlet. The edges of the nasal weapon are finely toothed, the upper side marked with numerous striae, the under side smooth but with a groove along the middle. The sides of the head are vertical, the eyes are round, the gill-covers, mouth and all the rest of the body covered with a rough skin, which is tuberculated in the very young specimens, but not in those which have attained any considerable size. The lateral line is hardly visible; the upper part of the body is shaded with bluish black, and the lower part is silvery white. The food, or at all events the substances which the sword-fish shows a disposition to seize as food, are very diversified, but the substances that have been actually found in the stomach have never been of great size. Small fishes and floating mollusca are what have chiefly been met with; but Captain Beechey, in his interesting narrative, mentions that "when in the Pacific Ocean, near Easter Island, as the line was hauling in, a large sword-fish bit at the tin case which contained our thermometer, but fortunately failed in carrying it off."

It is said that the sword-fish swim in pairs, and this is another ground for doubting whether they assemble in numbers to attack the whales; and even a pair have rarely, if ever, been seen together in our seas. If we can believe the reports, they sometimes ascend the rivers; for Daniel, in his "Rural Sports," mentions that a man, when bathing in the Severn, near Shrewsbury, received a mortal wound from a sword-fish. This, if true, is a very curious matter, as the wide sea, and not even the shores, or the shallows over the banks, are the natural habitat of these fishes.

In the Mediterranean, where they are much better known than in any other of the European seas, they approach the shores in May, and continue for about three months; and the capture of the old ones, which are sometimes at least four hundred pounds in weight, is a matter of some enterprise. The fishermen have their boats provided with harpoon and line; and the mast of a vessel, or a high cliff overlooking the sea, is taken possession of by the man who is on the lookout. When he makes the signal, the boats run to the spot, and the harpoons are launched, till one takes effect. The fish, when struck, darts off, though not so rapidly as the whale, neither does it plunge like that animal. But the sword-fish is more wary than the whale, and presents a much smaller object to the marksman, so that the hitting of it requires no little skill; and it often continues to swim and struggle for several hours before they can completely subdue it. The flesh of the large ones, like that of most animals of rapid motion, is hard and dry, though wholesome, and not disagreeable to the taste; but that of the young, even when of very considerable size and weight, is said to be excellent.

CENTRONOTUS. This is also a numerous genus, which is subdivided into four subordinate genera, *Naucrates*, *Elacati*, *Lichia*, and *Trachinotus*. The leading characters of the genus are: the first rays of the dorsal fins free, or without any membrane, and the ventral fins always present. Our limits will admit of a notice of only one species of one of the sub-genera.

Naucrates ductor—the Pilot-fish. The generic characters are: the scales small, one long dorsal, with

some pure rays in the anterior part, and four rays also in front of the anal; the sides of the tail with a keel, and the teeth numerous, but small.

The pilot-fish is one which has been long celebrated. The Greeks, who were always ready to throw in a little embellishment upon the very slightest grounds, regarded it as a sacred fish, and one which was of essential service to doubtful voyagers. Modern science has, of course, bereaved the fish of much of its reputed glory in this respect, by showing that the ship is pilot to the fish, and not the fish to the ship; but even now the pilot-fish is looked upon with a good deal of superstition.

It follows sharks as well as ships, and for the same reason, no doubt, in both cases, namely, for the refuse that it can pick up. The teeth of the shark have a cutting or mangling structure, and thus portions of its prey escape, which these comparatively small, but active and voracious fishes, readily seize. It appears, therefore, that the pilotage which this fish gives to the shark is very much akin to the providing which it used to be said the jackall made for the lion—the hope of sharing in the capture made by the more powerful animals. The stories which are told point, however, to something very different from this, and, as they are told and reported by those who are really the best authorities on the subject, we shall mention at least one of them. The stories which are told of the efforts made by these pilot-fishes to tempt the shark to take the bait which is thrown out in order to catch him, have some semblance of truth about them, because they approach and hover about the bait, though they are unable to take it on account of its size; but it must not be supposed that they in any way tempt the shark, either to his destruction or for their own personal advantage; and the last of these is the only one for which there could be anything like a rational ground, even supposing that the pilot-fish were actually possessed of speculation, which it evidently cannot be.

But the opposite accounts, namely, those of the pilot-fish attempting to keep the shark from the danger of the hook, have more of romance in them, and are sometimes told in a more circumstantial manner; so we shall quote one in the words of Colonel Hamilton Smith, whom Cuvier calls “très-savant naturaliste.” It occurs in Griffith’s *Animal Kingdom*, vol. x. p. 636, and is in these words:—“Captain Richards, R.N., during his last station in the Mediterranean, saw, on a fine day, a blue shark which followed the ship, attracted perhaps by a corpse, which had been committed to the waves. After some time, a shark hook, baited with pork, was thrown out. The shark, attended by four pilot-fish *Scomber ductor*, repeatedly approached the bait; and every time that he did so, one of the pilots, preceding him, was distinctly seen from the topsail of the ship to run his snout against the side of the shark’s head, to turn it away. After some further play, the fish swam off in the wake of the vessel, his dorsal fin being long distinctly visible above the water. When he had gone, however, a considerable distance, he suddenly turned round, darted after the vessel, and, before the pilot-fish could overtake him and interpose, snapped at the bait, and was taken. In hoisting him up, one of the pilots was observed to cling to his side until he was half out of the water, when it fell off. All the pilot-fishes then swam about a while, as if in search of their friend, with every apparent mark of anxiety and

distress, and afterwards darted suddenly down into the depths of the sea. Colonel H. Smith has himself witnessed, with intense anxiety, an event in all respects precisely similar.”

This story of “the friendship of the fishes” outdoes all that Canning ironically said of “the loves of the triangles;” but we are constrained to suspect that there are circumstances in the narration which tend to invalidate the truth of it in the sober history of nature, though it may be all very well as a sailor’s “yarn.” In the first place, would a shark follow a ship attracted by a corpse which was not in the ship, but had been committed to the deep? In the second place, do sharks really follow ships, when there are corpses on board, more than they do at other times? and if so, by what particular organisation does a fish in the water continue to nose out the particular origin and direction of an effluvium, whatever that effluvium may be, which affects the air from a vessel in motion? In the third place, how was it known that the pilots would have interposed to prevent the shark from taking the bait, when they did not so interpose? And, in the fourth place, how far “down into the depths of the sea” did the pilots go to spend the time of their mourning for the loss of the shark? A satisfactory answer to these questions is the first desideratum toward a fair understanding of the manners and motives—no, *not* motives, for motives it can have none—of the pilot-fish; and when these have been all answered in the most full and satisfactory manner, it is only a beginning of the questions which present themselves, each more eager for an answer than another. These we cannot discuss.

We must, however, quote a passage from Mr. Yarrell illustrative of the partiality of the fish for ships, though he avoids the grounds of this partiality, “In the year 1831,” says Mr. Y., “two specimens of the pilot-fish were caught on the opposite side of the British Channel; and more than one instance has occurred of their following ships into Guernsey. A few years since, a pair accompanied a ship from the Mediterranean into Falmouth, and were both taken in a net. In January, 1831, the *Peru*, Graham master, put into Plymouth, on her voyage from Alexandria to London, after a passage of eighty-two days. About two days after she left Alexandria, two pilot-fish, *Gasterosteus ductor*, made their appearance alongside the vessel, were constantly seen near her during the homeward voyage, and followed her into Plymouth. After she had come to an anchor in Cutwater, their attachment appeared to have increased; they kept constant guard to the vessel, and made themselves so familiar, that one of them was actually captured by a gentleman in a boat alongside, but, by a strong effort, it escaped from his grasp, and regained the water. After this the two fish separated; but they were both taken the same evening, and, when dressed on the next day, were found to be excellent eating. In October, 1833, nearly one hundred pilot-fish accompanied a vessel from Sicily into Cutwater, but they were not captured.”

Discounting all the romance which has been coupled with the pilot-fish, there remains enough of reality about it to entitle it to no small degree of attention; and though it would be perfectly ridiculous to suppose that the fish has any attachment to the ship, or to those who are on board, yet the fact of a little fish following a vessel for more than two thousand miles is a curious one. It is also a fish of

some interest in another point of view. When recently out of the water it is very good eating, resembling very much the common mackerel. Its principal food consists of small fishes, in quest of which it appears to range extensively. It is said to be by no means rare off the south coasts of Britain during the summer months; but it rarely comes so near the land as even the remotest places where the regular fishing is carried on.

Pilot Fish.

The pilot-fish is generally about a foot long. The general colour greyish-blue, with a silvery lustre, and paler on the under part; the body is marked with five distinct blue bands, much darker than the ground colour, which completely surround the body, at right angles to the axis, and are of uniform breadth, and parallel to each other; there is also a trace of one obscure band on the head and another on the tail; the snout is blunt; the under jaw projects farther than the upper; the eye, which is one-fifth of the depth of the head, is twice as far from the posterior edge of the gill-cover as from the extremity of the nose, and the irides are golden yellow; the gape not very deep; the teeth small, but numerous, forming a band upon each jaw; and there are also teeth on the palatal bones, and one large one on the vomer and another on the tongue; the tongue is large, thin, and free; the scales are small, and of an oval shape, with the exception of a triangular spot at the base of the pectorals; the cartilaginous keel upon each side of the tail reaches from the last rays of the dorsal and anal fins to the extremity of that organ. Though this fish is very much distributed over the different seas, there are not many changes in its appearance arising from change of place; but it appears that the name has been sometimes given to more than one species.

None of the others of this genus are met with in the British seas even as stragglers, and therefore we shall pass them over very lightly. *Elacata* are very like the pilot-fish in many respects; but they have not the fore spines in advance of the anal fin, nor the cartilaginous keels on the sides of the tail. The members of this sub-genus are found chiefly in the American seas. *Lichia*, have free spines on the back, and also at the fore part of the anal fin, and they have an additional spine on the back in advance of the others, and curved forwards. The body is compressed, and there are no lateral keels on the tail. There are three species of the sub-genus, natives of the Mediterranean, and all held in much estimation as food. One of these, the *Vadigo*, which is the typical species, attains a length of four feet or upwards, and a weight of a hundred pounds; it is a thick fish, and has the lateral line in a curve of contrary flexure, like the letter ∞ . Another, the *Dorchis*, has the lateral line nearly straight; the teeth small and arranged like velvet; and a black spot on

the anterior part of the second dorsal fin and the caudal. A third, has the lateral line waved into zig-zags; the upper part of the body blue, and the under part silvery; and the teeth large compared with those of the others, and in a single row. Others, with the base of the forehead more abrupt, and the body more compressed, are found in the Indian seas, where they are well known to the fishermen.

NOTOCANTHUS. Of this genus there is only one known species; which, contrary to the general habits of the family, is found only in the seas of the very high latitudes. The characters are:—the body long and compressed, and covered with small smooth scales; the muzzle blunt, but projecting in front of the mouth; the teeth small and thickly set; free spines on the back only, and the ventral fins placed far backwards.

SERIOLA. The characters of this genus very much resemble those of the genus *Lichia*. Like that, they have a crooked spine on the back, in advance of the dorsal; but the first rays, instead of being free, as in that genus, are united by membrane. They have also a little detached fin supported by the spinous rays of the anal. The body is compressed, and without any keel or other armature on the dorsal line. There are several species of this genus, all found in the warmer seas. One in particular, the *milk perch* of the Coromandel coast of India, is held in much estimation for the superior quality of its flesh, which is white, and said to be of the most exquisite flavour. One species has been found in the southern seas, which has the first ray of the dorsal and the anal detached, and bearing a little fin.

NAMEUS (the herdsman or shepherd). These fishes have many of the characters of the preceding genus; but they have the ventral fins very large, whit their inner margins attached to the sides, which is sufficient to distinguish them from all the others.

The herdsman, which is a native of the American seas, has acquired a celebrity something similar to that possessed by the pilot fish, only it is much less discursive; and has not been observed to follow ships to the shores of Europe, or even into the wide expanse of the Atlantic. The set of the tides and currents in that ocean are, indeed, rather against the passage of American fishes eastward; and, consequently, few of them visit our shores. The colour of this fish is silvery, with black bands across the back; and it is the "banded mackerel" (*Scomber fasciatus*) of some authors, and the (*Gobius Gronovii*) of others. It is not rare upon many parts of the east coast of America, from the equator to pretty high latitudes; and it attains the size of the salmon. The set of the Gulf stream along the coasts of the United States, and the higher temperature of the water in that stream, cause a very general distribution of tropical fishes along the whole line.

TEMNODON (open-tooth). This is a genus of which only a single species is well known; but it is very generally distributed, and that has caused it to be called by many names. It is found in the Mediterranean, on the coasts of the United States, of Brazil, of Southern Africa, and of Australia; and, widely as these localities are distant from each other, there does not appear to be the least elongated variation in it. It has been called the "leaping perch," the "southern perch," the "leaping gilt-head," and many other names; but its family characters are those of

the *Scomberoidæ*, and its generic ones are peculiar. There is no keel on the tail; the first dorsal fin is low and feeble, and the second dorsal and the anal are covered with small scales. The principal characters, however, are those of the mouth. The external part of both jaws is furnished with a row of large teeth, with sharp or trenchant points, and standing at some distance from each other. Within these, there is another row of smaller ones; and the vomer, the palatal bones and the tongue, are all thickly set with very minute teeth. So powerful an armature of the mouth, betokens voracity in feeding and variety in the food. The fish is a very active one, and springs to a considerable height out of the water.

CARANX. The fishes of this genus are well known on the coasts of many parts of Europe, and they are far from being rare on those of Britain. They are called "False Mackerel," or in Britain, "Horse Mackerel;" and they are taken much in the same manner, but are considered as being fishes of very inferior quality. The leading generic characters are: the body covered with small scales; the lateral line having a row of broad scaly plates, which are marked with a keel on the hinder part of the body. These scaly bands are very conspicuous, and extend to the origin of the central rays of the caudal fin, narrowing as they reach that part. The number of these lateral plates varies in the different species; and in some, the keel is drawn out into a spine upon each plate. There is one spine curved forward in advance of the first dorsal, and two free spines inclining backwards in advance of the anal. The abdominal fins are under the pectorals. There are two distinct dorsals, the front one short, and the second long, beginning opposite to the anal spines, and extending nearly to the beginning of the caudal; as also does the anal, which resembles the second dorsal both in form and in size, only the first rays are rather longer in proportion.

This genus is widely distributed; but, unlike the former genus, the species vary much in the different localities, and there are different ones in the same locality. Only one can be regarded as decidedly British, and we shall restrict the few particulars which we can afford to this one.

The Scad, or Horse-mackerel (*Caranx trachurus*). This fish is not a favourite article of food; and thus it is seldom taken in proportion to the numbers in which it actually exists, and rarely even in proportion to the numbers which are caught. We believe there are but few places in Britain where it is eaten at all, and none where it can be properly called a marketable fish; though they are called so in some places. Generally they make their appearance in parties which are not very numerous; but at other times, they are in immense shoals, and might be taken in vast quantities. A communication from Mr. Bicheno to Mr. Yarrell, is so graphically descriptive, that we shall quote it: "On Tuesday the 29th of July, 1834, we were visited by immense shoals of Scad, or as they are also called, Horse-mackerel. They were first observed in the evening; and the whole sea, as far as we could command it with the eye, seemed in a state of fermentation with their numbers. Those who stood on some projecting rock, had only to dip their hands into the water, and with a sudden jerk they might throw up three or four. The bathers felt them come against their bodies; and the sea, looked

on from above, appeared one dark mass of fish. Every net was immediately put in requisition; and those which did not give way from the weight, were drawn ashore laden with spoil. One of the party who had a herring-seine with a two-inch mesh, was the most successful; every mesh held its fish, and formed a wall, which swept on the beach all before it. The quantity is very inadequately expressed by numbers, they were caught by cart-loads. As these shoals were passing us for a week with their heads directed up channel, we had an opportunity of noticing that the feeding time was morning and evening. They were pursuing the fry of the herrings, and I found their stomachs constantly full of them."—This is one of the very best accounts of a shoal of fish that ever was written; and it refutes the opinion stated in many of the books that the scad is a rare fish. They are found all round the coasts; making their appearance, in small straggling parties, as early as April; but not coming in their full numbers till the hot season. They are very vigorous swimmers, and run on the shores or shallows, and entangle themselves much more frequently than herrings. They do this, not by being caught in storms, which is said to be the cause of grounding in the herrings, but in eager pursuit of their food. The upper part of the scad is clouded with olive, and green and blue, passing into silvery on the under part and the sides of the head. The upper fins dusky, the lower very pale; a large spot on the gill-cover just over the temporal fin, and also the throat and bottom of the under jaw are black. When the fish are on the coast, they are very readily taken with hook and line. The spawning time is in the very heat of the summer.

Nearly related to this section of the family, if not actually belonging to it, there are numerous fishes of the tropical seas; but the history of them is very confused and imperfect, even among the professional zoologists; and therefore, it is by no means a fit subject for popular disquisition. There is a very high degree of interest about the fishes which range the wide ocean, and are endowed with powers that enable them to stem the vast swell of these mighty waters; but their pasture is co-extensive, and seen at so few points, that their history will be long in arriving at any thing like perfection.

VOMER (Ploughshare-fishes). This genus has been formed for the purpose of receiving a considerable variety of fishes, still having the family characters of the *Scomberoidæ*, but differing greatly in their appearance from the typical mackerel; and there is a gradation among themselves which made Cuvier feel it necessary to divide them into six sub-genera, placing those upon which the name is founded last in the order of arrangement. The progressive change in them is, that the lateral line becomes less and less armed with keels, plates, or appendages of any kind; the body more compressed and deeper in proportion to the length, and the skin smoother and more free from scales. Most of them, too, have part of the rays of the fins produced to a very great length; and the teeth are small, and thickly set together like smooth velvet. The earlier naturalists, who had but few opportunities of observing the fishes of distant seas, included all these in the genus *Zeus* or *Jupiter*, which has now been separated; and even that genus, restricted as it now is, has been very conveniently divided into five subgenera. This part of the family of the *Scomberoidæ* is, indeed, quite a puzzle, because

there are many of the prolonged appendages of which it is difficult to imagine the use.

There is even an intermediate sub-genus, which one can hardly refer either to *Caranx* or to *Vomer*; and there are two species of *Caranx*, both natives of the warm seas, the distinction of which is well worthy of attention. There are the *true* and the *bastard Carangus* of the West Indies, the mistaking of the one of which for the other is a much more serious matter than the mistaking of the scad for the mackerel. The true *Carangus* is a fish of a silvery colour, with a black spot on the operculum. It attains considerable size, reaching twenty-five pounds in weight; and it is an excellent fish for the table. The other one, which resembles this in many respects, but never has the spot on the gill-cover, is poisonous. If these had been fishes of the European seas, they would have helped to give more of romance to the fable about the marks of the Apostle's thumb and finger on the fish, when he took the tribute-money out of its mouth; for if, as could have easily been fabled in this case, the fish had been changed from poisonous to sanative at the same time that it got the thumb-mark, the whole would have made a capital monkish miracle.

The species which appear to be intermediate between the true *Carangi* and the *Vomers*, are East Indian. Some of them are entirely without teeth; and others, to which Cuvier has given the sub-generic name of *Citulus*, have the points of the second dorsal and the anal very much produced.

Vomer he subdivides into six, as we have said: *Alistus*, *Seyris*, *Blipharis*, *Gallus*, *Argyreosus*, and *Vomer*, properly so called. *Alistus* have the middle rays of the second dorsal without any branching, but articulated, and produced into very long filaments. *Seyris* have similar filaments, but the stems of the first dorsal are entirely concealed in the anterior margin of the second, and their ventrals are short. Some of them, of very singular shape, are found in the southern parts of the Mediterranean. *Blipharis* have the same lengthened filaments in the second dorsal and the anal as the preceding; and in addition they have the ventrals very long. Their body is very elevated, and their profile singular. One of them is the "cobler-fish" of the West Indies—the *Zeus ciliaris* of Bloch. *Gallus* have the profile still more elevated, and the profile of the gape more oblique than the last; but in other respects they are nearly the same. *Argyreosus* has the profile more elevated still, and the first dorsal developed, and drawn out into long filaments in a manner very similar to the second. They have also the ventral fins very long. *Vomer* have the same shape in the body, but the fins are not produced into long filaments. All of these are fishes of most singular appearance; but very little is known of their natural history, or of the use which they make of their singularly produced filaments. They can at present be looked upon as little else than objects of mere curiosity; but there is no doubt that their singular forms are connected with a history equally singular if we could find it out.

Zeus—Dory. This genus is one of more interest than any of the preceding ones, on account of the estimation in which the leading species is held by the ichthyophagic epicures. Some account of this celebrated species will, however, be found on looking back to the article Dory in this work; and that will render any farther notice in this place unnecessary.

There is, however, a species of one of the other subgenera, which has usually occurred on the British

The Dory.

coast, and we may give a mere notice of it. This is

The Boar-fish (*Capras aper*) which is the only known species of the sub-genus *Capras*. The generic characters are: two dorsal fins, but without any filaments to the rays of the spinous one as there are in the Dory, and without any spines at the base of either the dorsal or the anal; the body oval in the profile, and much compressed, covered with small rough scales; the mouth capable of being protracted and withdrawn to a greater extent than in the Dory. It is in consequence of the power of lengthening and shortening the snout that this species is called the boar-fish.

Boar Fish.

The body is shorter in proportion to its height than that of the Dory; and the jaws are more lengthened when the mouth is open; the teeth are small, and at some distance within the margin of the jaws. The eye is very large, and about its own breadth from the extremity of the mouth when that is shut. The nostrils are close by the anterior part of the orbit, and have a considerable opening; the first dorsal, the pectoral, and the ventral, all have their origin in the same straight line, at right angles to the axis of the body; the surface feels smooth when the hand is passed over it backwards, but rough in the other direction. It is a small fish, not above six or seven

inches in length ; but it agrees with the rest of the genus in being of discursive habits, and a fish of much power in the water. The colour is brownish yellow, without any black spot like that which characterises the Dory ; but though it is a very inferior fish to the Dory, there is not the same distinction between the spotted and the unspotted as there is in the *Carangi* of the West Indies. The flesh of the boar-fish is hard and not relished ; but it has no poisonous quality. Some of the authorities mention that the odour of it is unpleasant.

This species has been known as an inhabitant of the Mediterranean since the days of Aristotle ; and a figure of it was given by Rondeletius in his work on fishes, published in 1554. The year 1825 is the earliest time mentioned of its occurring on the south coast of England ; but as several have been noticed since that time, the probability is that want of observation, not want of fish, was the real cause of its not being noticed before.

Lampris is the third of Cuvier's sub-genera of *Zeus*. As is the case with the preceding sub-genera, there is only one species of this ; but authors have made amends, as far as they could, by bestowing upon this one a number of names. The characters are : the body oval and much compressed, covered with small scales ; a single dorsal fin, elevated in the anterior part and falcate ; the pectoral and ventral fins and lobes of the tail rather long ; the sides of the tail with a keel ; and the mouth destitute of teeth. The species alluded to is

The King-fish or Opah (*L. guttatus*). This is a very discursive fish, being found in the Atlantic and the Pacific ; and in many latitudes, especially in the former. It is a common fish on some parts of the west of Africa, and it also appears as far to the north as the coast of Norway. On the British coasts it has hitherto appeared so indiscriminately in various places, that one cannot say that it comes from any particular direction, although the south and west may be set down as the coasts upon which it is most likely to be found.

It gets its royal name from the beauty of its colours, which are certainly as rich as one can well imagine. The upper parts, when seen with little reflection of light, are of a greenish colour ; but as the position is shifted, there come out rich metallic reflections of purple and gold. The under part is greenish yellow, into which the richer colours of the upper part fade gradually, and the metallic reflections become less brilliant as this colour gets pale. Along the sides, both above the lateral line and below it, there are round spots of white, very well defined in their outlines. The fins are rich vermilion red, and the irides scarlet. The body, seen in profile, is of an oval form, or rather composed of two similar symmetrical curves, which meet in a blunted angle at the snout, and approach each other at the base of the tail, where the depth is not great. The greatest depth of the body is in advance of the middle of the length, and measures about half as much. The lateral line is much curved, rising near to the dorsal fin, opposite its base, and again descending toward the upper edge of the gill-cover. The fish is of huge size and weight, one specimen having occurred in this country measuring four feet and a half in length, and weighing one hundred and forty pounds.

Equula is the next sub-genus into which *Zeus* has been divided. They have only one dorsal fin, but

that contains many rays, and the anterior ones are often very elevated. The body is compressed, and the upper and under lines are toothed in many of the species. The muzzle in all is protractile, and some of them are said to make use of it in capturing the small fishes and other little animals upon which they feed. They lie in a state of repose, with the muzzle drawn in to the utmost that it admits of, and when the prey comes within their reach, they shut the muzzle at it, and seize it with great accuracy. The species are numerous, generally of small size, and most of them inhabit the Indian seas.

Mene have the muzzle formed like *Equula*, but differ from them in many other respects. They have the body still more compressed, and the back nearly straight, which gives the outline of the under part a very great degree of curvature ; and the position of the shoulder bone and the cavity of the body, throw the abdominal fins in advance of the pectorals. There is but one known species, a native of the Indian and Chinese seas. It is of a fine silvery colour, with black spots on the back.

STROMATEUS. These fishes have the compressed form of the genus *Zeus*, but the muzzle is blunt and not protractile, and their teeth, which are very small, are in a single row. The spinous rays of the dorsal are nearly concealed in the anterior margins ; they have no ventral fins. They admit of subdivision into numerous genera. The greater part of them inhabit the warm seas, though there are some in those of Europe, which, however, are too rarely seen for having any thing like a popular history.

KURTUS—Hunch-back. These resemble the last mentioned genus in many points ; but they have also many peculiarities. Their dorsal is much lower ; their ventrals are large ; and their anal long ; the scales upon them are so minute, that they cannot be seen till the gelatinous parts shrink on drying the skin ; they have a spine on the under part between the ventrals, and little sharp horns in advance of the dorsal, and a crooked spine immediately in front. They have a cavity formed by rays of the rib under the spinal column, in which the air-vessel is lodged. The typical genus is *Kurtus cornutus* of India ; so called from a sort of horn, which occupies the place of the front cartilaginous projection in advance of the dorsal. This species feeds upon crustacea and shelled mollusca. In point of colour it is a very beautiful fish. The scales have a silvery lustre more perfectly metallic than is to be found in almost any other fish ; and this is set off by fine contrasts. The pectoral fins are metallic golden yellow, bordered with red ; the other fins are yellow with black borders, and having little metallic lustre.

CORYPHÆNA is the last genus of the mackerel family which contains many species, most of them inhabitants of the warm seas ; many of them fishes of large size and great beauty, and all of them possessing in a high degree that muscular power which is characteristic of the family. Some notice of the sub-genera, and also of the leading species, will be found in the article *CORYPHÆNE* ; so that it only remains to notice one species which claims to be a British fish, though a very rare one. This species is

The Black Fish (*Centralophus pompius*). The characters of this genus are : no teeth on the palate, and those in the jaws very small ; a single dorsal, rising at some distance behind the occiput, and long, but not very high ; no spines in front of the dorsal or the

anal; and the body covered with small scales. Only a few specimens are mentioned as having occurred in the British seas, and all in the west of Cornwall. They have been of different sizes, some only fifteen inches in length, and others two feet eight, the latter weighing nearly fourteen pounds. The skin of this fish is very tough and strong, and can be taken off like that of an eel. The flesh is of very superior quality. The snout is blunt and rounded; the gape small; the teeth very fine; the tongue large; nostrils double, and that nearest the eye the largest; the eye bright and prominent; the head flattened on the upper part; gills with five rays; body compressed, with the base of the dorsal fin on a ridge; the base of the dorsal about half the length of the fish; pectoral fins pointed; ventral confined by a membrane; tail forked. The whole body black, scarcely lighter on the belly, and very intense on the fins. The colour fades to blue, however, after the fish has been for some time out of the water. This disposition to change in the colour, has occasioned some perplexity in the description of the fish. In warmer seas it has a fine play of iridescent colours, which pass off, however, as the fish dies. These glosses of colour are common to the whole mackerel family, but they are more conspicuous in the Coryphenes than in any of the others. They are probably connected with the energy of the principle of life in these fishes, and the powerful influence which, considering how near the surface they swim, the sun must have upon them; but this connection between energy of life and play of colour, though a very curious subject, is one which has not been as yet much investigated.

The black fish is very swift and powerful in the water. One taken in a salmon net at East Looe in 1830, showed great power of action, and would have dashed its way through a net of weaker structure. What may be the numbers of this species in the sea, we have no means of ascertaining; but from the size which they attain, and the very superior quality of their flesh, it were very desirable to find out their haunts, if they do congregate in numbers in any part of our seas. It follows, of course, from the energy of their characters, that they are very rapacious; and it has been ascertained that they are miscellaneous in their feeding, eating not only small fishes and mollusca, but even sea-weed. Thus, if the places where they are in numbers could be ascertained, they could be easily taken with hook and line.

Such is a very abridged outline of the mackerel family, especially of such members of it as are found on the British shores; the full illustration would demand a separate work exclusively devoted to the subject; and, readily as most of the species show themselves, much remains to be done before such a work could be made worthy of its subject.

SCORPIO (Linnaeus). A genus (or rather **SCORPIONIDÆ**, Leach, a family) of arachnidous insects, belonging to the order *Polymerosomata*, Leach, or *Pedipalpi*, Latreille (see **ARACHNIDA**), having the abdomen attached by its entire breadth to the thorax, furnished on the under side with two moveable comb-like plates, and terminated by an elongated and knotted tail, the extremity of which is armed with a curved and very acute sting. The breathing pores are eight in number, arranged four on each side along the belly; the arms (or palpi, very greatly developed) are of very large size, serving as instruments of

prehension, and terminated by a large claw. The legs are eight in number, of moderate size, and much larger than the palpi. The eyes are eight in number, three on each side of the thorax, and two on the back. The "antennæ-pincers" are terminated by two fingers, one of which is moveable. The abdomen (including the tail) is composed of twelve segments. The use of the curious comb-like appendages has not yet been determined.

The scorpion is one of the most renowned amongst the obnoxious of the insect tribes. Fortunately for our country no species is found amongst us, although in Germany, and several other parts of Europe, it is too well known. This exemption is consequent upon our northern climates, since it is chiefly in tropical, or at least in hot regions of both hemispheres, that the various species are found, and in the former they occasionally attain a very large size. They reside on the ground in sandy districts, and hide themselves by day under stones, logs of wood, &c., especially in dark places, and often in houses. They run very quickly, and, when alarmed, throw their tail over the back, twisting it about in every direction, and using it both as an offensive and defensive weapon. They make use of their claws to lay hold of insects upon which they feed, and which generally consist of ground-beetles, cockroaches, &c., which they first wound with their sting, and then convey to their mouth. They are also especially fond of the eggs of spiders and other insects. They propagate in some localities so quickly as to become a constant cause of dread, even occasionally compelling the inhabitants to quit their abodes. These animals were well known to the ancients, and the zodiacal constellation of the Scorpion will convince us that a knowledge of these creatures must be attributed to the earliest periods of science. In the Egyptian mythology they are represented as the symbol of the genius of evil. Pliny has collected all the fables which ignorance and superstition combined had attributed to these creatures, and on the authority of Apollodorus he distinguished nine species. Nicander added another, and detailed the supposed medical virtues of the animal. The existence of scorpions with two tails is not entirely fabulous, since there exists in the Museum at Paris a specimen (a monstrosity, of course) in which this singularity of malformation is exhibited. The winged scorpions which Megasthenes stated that he discovered in India, and which were affirmed to be of a very large size, were in all probability nothing else than some large *Phasma*, or perhaps one of the gigantic exotic *Nepidæ*.

In France the *Scorpio Europæus* appears about the forty-fourth degree of latitude, in that zone where the almond tree and pomegranate are capable of cultivation, and nearly equal with the most northern limits of the olive.

There are few animals more obnoxious than the scorpion, especially in tropical climates, where it often attains to a very large size. In Batavia, where they are stated to attain the length of twelve inches, there is no removing any piece of furniture without the utmost danger of being stung by them. Bosman assures us that along the Gold Coast they are often found larger than a lobster, and that their sting is inevitably fatal. In Europe, however, they are by no means so large, so venomous, or so numerous. The general size of the European scorpion does not exceed two or three inches. Manpertuis, who made

several experiments on this species, found it by no means so invariably dangerous as had till then been represented. He provoked one of them to sting a dog in three places of the belly, and in about an hour afterwards the poor animal was greatly swollen, and became very sick. Afterwards it fell into convulsions, bit the ground, dragged itself along on its fore feet, and at last died, five hours after being stung. It was not partially swollen round the place which was wounded, as is usual after the sting of a wasp; but the whole body was sufflated, and there appeared only a red spot on the places where it had been stung. The experiment was, however, repeated upon another dog, even with aggravated cruelty, yet the dog seemed in no way affected, howling only a little when stung, and without showing the smallest symptom of pain. The same experiment was also tried by fresh scorpions upon seven other dogs and three hens, but not the smallest deadly symptom was seen to ensue. Hence it is evident, that although, in the majority of cases, the sting of this insect may not be greater than that of a wasp or hornet, yet, in certain cases, and under certain unknown circumstances, either connected with the state of the animal stung, or of the scorpion itself, a far greater efficiency is given to the sting.

The scorpions of tropical climates being much larger than the former, are probably much more venomous. Helbegius, however, who resided many years in the East, asserts that he was often stung by the scorpion, and never received any material injury from the wound; a painful tumour, however, generally ensuing. Seba, Moore, and Bosman, however, state that, unless speedily relieved, the wound becomes fatal. The *Scorpio occitanus* of Latreille, found in the south of Europe, Barbary, &c., has been experimented upon by Dr. Maccari, who allowed it to sting himself, and which produced alarming and painful symptoms. Moreover, the venom appears to be more active in proportion to the increased age of the animal. Volatile alkali, applied both internally and externally, is employed as a serviceable remedy. The Persians use, for curing the sting of the *Scorpio australis*, Linnæus, which they call *Agrab*, and the Indians *Gargondali*, scarification and quicklime; others make use of oil, in which several of these creatures have been steeped; and others bruise the scorpion, and apply it to the wound.

It has been a vulgar notion, that a scorpion enclosed in a circular space by burning charcoal, would sting itself to death. Maupertuis, however, and, more recently, M. Guérin, have combated this idea, observing, that in such cases the scorpion only runs about in a very quiet state, and is at last killed by the heat. The Count de Senneville is, however, stated by Latreille to have made the same experiment in the presence of a great number of persons, and the result has always been the death of the scorpion, produced by stinging itself. It is certain that their stings are sufficient to destroy their companions; for Maupertuis confined about a hundred of them in the same glass, and they soon came into contact with one another. When they began to exert all their rage in mutual destruction, there was nothing to be seen but universal carnage, so that in a few days there only remained fourteen, which had killed and devoured all the rest; and on certain occasions their malignity is extended even to their offspring. The female brings forth her young alive,

and of the same form as herself, varying in numbers from twenty to forty; and Maupertuis states, that having enclosed a female in a glass vessel, she was seen to devour her young as fast as they were excluded, one only escaping by taking refuge upon the back of its parent; and this soon after revenged the death of its brethren, by killing the old one in its turn. Ordinarily, however, the female is much more solicitous concerning her offspring, bearing them about for several days upon her back, seldom quitting her retreat, and tending them for the space of a month, by which time they are sufficiently strong to take care of themselves. They shed their skins annually, and are not enabled to reproduce their species until they are two years old.

The species of this family are numerous. Herbst has published a good monograph of them, with coloured figures. Dr. Leach has divided them into two genera; *Scorpio*, having only six eyes, of which the *Scorpio Europæus* is the type; and *Buthus*, having eight eyes, of which the scorpion of Maupertuis (*Scorp. occitanus* of Amoreux) is the type. The former species does not exceed an inch in length, is of a black brown colour, the legs being fulvous, and the combs having nine teeth.

SCORPION-FLY. See PANORPA.

SCORPION (Water). See NEPA.

SCORPIURUS (Linnæus). A curious genus of annuals, bearing diadelphous flowers, and belonging to *Leguminosæ*. They are cultivated for the grotesque shape of their pods, which bear a strong resemblance to caterpillars.

SCORZONERA. A genus of perennial herbs, known in English lists by the name of viper's-grass. They bear composite flowers, and one of the species, *S. hispanica*, is cultivated for its roots, which are considered a dainty.

SCROPHULARINÆ. A rather extensive natural order, containing fifty-nine genera, and above five hundred and fifty species. A great part of Linnæus's *Didynamia angiosperma* is found in this order; capsular fruit and didynamous stamens being among the most obvious characteristics of the order. The genera are herbaceous (rarely shrubby) plants with round or square stems; the leaves are simple and without stipules, sitting, or with footstalks, and sometimes decurrent; in situation opposite or whorled, seldom alternate.

The inflorescence is variable, axillary or united, usually spicate, racemose, or in panicles; the calyx is free and persistent; the corolla hypogynous, often bilabiate, personate, and deciduous; the stamens are definite (two to four), didynamous, rarely equal, exserted from the tube of the corolla; the filaments are free, and the anthers two-celled; the germen is formed of two carpels, the style one, and the stigma obtuse. The fruit is capsular and dehiscent, two-celled, and from two to four valved. This order is divided into two sections; the first includes those genera which have four anther-bearing stamens, and the second those genera which have only two anther-bearing stamens.

SCURVY-GRASS is the *Cochlearia officinalis* of Linnæus, a medical plant found wild on the sea-shores of Britain, and belonging to *Cruciferae*.

SCUTELLARIA (Linnæus). A pretty extensive genus of herbaceous perennials, natives of many different parts of the world. They belong to the first order of *Didynamia*, and to the natural order *Labiatae*.

The greater part are hardy, and when brought into the garden are planted in the open borders.

SCUTELLERA (Lamarck; *TETRA*, Fabricius). An extensive genus of hemipterous insects, belonging to the suborder *Heteroptera*, and family *Pentatomidæ*, having, as the generic name implies, the scutellum very large, and entirely covering the dorsal portion of the abdomen and the wings. The habits of this group are similar to those of the *Pentomæ*, *Corei*, &c. The species are generally of large size, and often very brilliantly coloured. They are, for the most part, exotic. The genus has been much subdivided by Hahn, Laporte, and Burmeister. The type is the *Cimex maurus* of Linnæus.

SCUTIGERA (Latreille; *CERMATIA*, Illiger). A curious exotic genus of centipedes. See *CHILPODA*.

SCYDMÆNUS (Latreille). A genus of minute coleopterous insects, belonging to the section *Pentamera*, and constituting the type of the family *Scydmanidæ*, in which the antennæ are straight, thickened at the tips; the maxillary palpi very long and thin; elytra covering the entire abdomen, thus differing from the *Pselaphidæ*, with which they have been supposed to be allied. They are found in moss and in damp situations. The type is *Scydm. Hellwigii* of Latreille. Kunze and Denny have published good monographs of this curious genus.

SCYLLÆA (Lamarck and other modern authors). Is a naked mollusc, its body elongated, very much compressed, convex on its upper side, and provided with a narrow-channelled foot; the head is distinct, with two large ear-shaped tentacles divided at the external side; the mouth opens with two longitudinal lips, armed with a pair of very large semilunar lateral teeth; the organs of respiration are in the form of little tufts irregularly disposed on the appendages of the skin. Only one species is at present known, and it is extremely common in the Atlantic Ocean.

SCYLLARUS (Fabricius). A genus of macrourous decapod crustacea, probably constituting the type of a distinct family, having the body very broad and flattened in front, and the lateral antennæ converted into a large flattened and horizontal crest on each side, with the sides deeply notched; the legs are all simple, the anterior not being formed into a claw as in the majority of the crabs and lobsters. These curious crustacea are found in the ocean of tropical and moderate latitudes, where they burrow in the bottom of the sea, whence they come forth when the sea is calm in search of their prey. They swim with a leaping motion. They are eaten as shell-fish on the southern shores of France, and the flesh of *Scyllarus orientalis* is said to equal that of our choicest lobster. The type is the *Cancer arctus* of Linnæus. There are a considerable number of species.

SEAFORTHIA (Dr. Brown). *S. elegans* is a New Holland palm, introduced to our collections in 1822, and thrives in light sandy loam and heath mould.

SEAL (*PHOCA* or rather *PHOCIDÆ*, the seal family, as they admit of division into many sections, sufficiently distinguished from each other for being accounted separate genera). A very numerous family of aquatic mammalia, breathing air like the rest of the class and having warm blood, capable of living on land, where they often resort for the purpose of reposing, or basking themselves in the sun, but having their principal habitat in the water, and their bodies adapted for motion in that element rather

than upon the land. Considered as regards their structure, their principal habitat, and their motions, they hold a place intermediate between the land mammalia and the *Cetacea*, or whales. As they have all the three kinds of teeth, they, in this part of their structure, resemble the land carnivora, and they have not a little of the sagacity and research which characterise these animals. Cuvier has, accordingly, placed them along with the morces, as the last group of the placental carnivora, and immediately preceding the marsupial animals. Perhaps it may ultimately be found, that their characters are sufficiently distinct from those of all the other mammalia, to entitle them to rank as a separate order; but their place in the system is a matter of minor importance, so that the animals themselves are properly understood.

The members of the seal family are among the most numerous of all mammalia that attain any thing like an equal size; and the herds of bisons, antelopes, and other ruminating animals which congregate in numbers, are really nothing to those of the seals. On some parts of the British coasts, especially the more northern ones, they are plentiful; but in other places they literally swarm. Estuaries and straits are their favourite grounds, evidently because the fishes, which are more dispersed in the open seas, congregate in greater numbers in the currents of these narrow places. The fishes not only congregate there in passing from the one sea to the other, but they are generally more plentiful in such places as constant residents. The reason is obvious: those small animals upon which such fishes as do not eat other fishes feed, are most abundant in the runs of water in these places; and this, of course, brings both the fishes which feed upon the small matters, and those which feed upon the fishes that do. In the British Islands for instance, seals are most abundant in the streams, and the friths or straits between the islands; and they give the preference to places where there are rocks surrounded by the water, banks alternately covered and exposed, and lonely and covered shores. Not that they are timid animals, for though very watchful, they are not timid; but they love places where they can enjoy themselves in the sun or in the air, and get quickly into the water in case of any alarm. We have mentioned that they sleep on the banks, but they are never all asleep at the same time. There are always sentinels; and when they give the alarm, the whole shuffle into the water as fast as they can. Sounds appear to alarm them more than sights do; for one may row or sail close to the place where dozens of them are basking without any notice being taken; but, if a shout is set up, they are instantly in motion. A very cruel mode of capturing them, founded on this, is, or at least at one time was, practised on some of the rocky shores of Britain. The places where this dry-land fishing was carried on, were generally those where a steep but not very high breast of rocks ran in the middle of a beach, towards which it sloped at both ends. The seals, when they came to bask, shuffled up the sloping ends of the rock, and then lay upon the top in considerable numbers. The breast of the rock was set with large sharp pointed hooks, which were the traps for the seals. A man came as near to the rock as he could come without alarming them, and fired a musket, at the report of which, they scrambled over the breast of the rock, in order to reach the water, and numbers of them were taken on

the hooks ; from which the people removed their lacerated bodies at their leisure.

But though seals have long been familiar to the inhabitants of the coasts of most countries, their natural history was long exceedingly obscure, and still is so in many respects ; and the species, which are naturally numerous, have been rendered still more so by the description of them from single museum specimens ; in which the same species was often described as if it had been many, in consequence of the variations of colour, from age, place, and season. Indeed a seal, immediately out of the water, is not of the same colour as one which has been exposed to the air till it is completely dry ; and in the former state, the shade of colour depends a good deal on the position of the light in which the animal is seen. In endeavouring to class them, we must therefore leave colour out of the question, and attend to differences of structure only. The most obvious structural difference, is the presence or the absence of external ears ; and accordingly, this has been taken as the foundation of two sub-genera,—the name *Phoca*, seal, being restricted to those which have no external ears ; and the name *Otaria*, eared-seal, given to those that have them. It does not appear, however, that any thing important can be founded on this external distinction ; for, as we have said, the common seal of our own shores hears very well, and it belongs to the division which have not external ears.

The different lengths of the muzzle have also been made grounds of distinction ; and probably, with better reason than the presence or absence of the external conchæ of the ears ; but still the differences of habit which depend on the peculiar development of this part, have not been ascertained, and therefore, it can be regarded as little else than a part of the detached description of the species.

The teeth vary a good deal ; but then the variation is so gradual that it is not easily made the ground of a clear distinction, which shall carry a difference of habit along with it ; and without this as its natural distinction, is of very little value.

All the members of the seal family have the three kinds of teeth, incisors, canines, and cheek teeth, but the cheek teeth can in no instance be considered grinders. Their crowns always consist of tubercles more or less developed and separated from each other, and never have a grinding surface, or one so well calculated for bruising, as the tuberculated teeth of the land carnivora. The canines, too, though large and powerful, are not so completely wounding or killing teeth as those of the land animals ; they have the curvation backwards more sudden and nearer the point, and thus they have a great deal of the character of prehensile instruments. In some the incisors are six in the upper jaw, and four in the under ; in others there are six above and only two below, and in others, again, there are four in each jaw. The canines are two in each jaw, and never wanting in any of the species. The cheek teeth are sometimes four in each side of each jaw, sometimes five below and six above, and sometimes six in both. There is another distinction of the teeth which is probably of more importance than any of these ; and that is the form of the roots, though the differences in this respect are generally accompanied with differences in the crowns. In those which have the crowns most trenchant, or with the tubercles most completely developed and detached at their points,

there are generally several roots or fangs : while in those that have the crowns more simple, there is, generally speaking, only one root. The chief difference in the habits supposed to be connected with this difference in the general character of the teeth, is that the trenchant teeth with several roots indicate more of a terrestrial habit, or nature, at all events, and those with the single rooted teeth more of an aquatic one.

But, notwithstanding these slight distinctions in the form of the teeth, the food and manner of feeding in the seals are very much alike in all the species. It has been said that some of them eat the more succulent kinds of sea-weed, which may be true, as some fishes which feed generally upon animal substances do the same. But there is little doubt that the staple food of the seals is fish, captured alive in the free waters, an operation in which they are very expert, as any one may see, who chances to observe seals hunting salmon, when the latter are on their march upward in the estuary of a river.

M. F. Cuvier has investigated the anatomical structure of the seals with very great attention, and in as far as classification can be founded on that, his divisions appear to be unexceptionable. But it must be admitted that every classification of this kind is in its very nature imperfect, as it does not reach the habits of the animals, which of course can be studied only in living nature. In this, comparatively little has been done ; for though seals are objects of no small commercial interest in the higher latitudes both of the northern hemispheres and of the southern, those who go to capture them pay no further attention to them than endeavouring to kill the greater part of their numbers, which are all valuable for the quantity and quality of their oil, and the use of their skins as leather or as fur.

He makes seven subgenera of the genus *Phoca* ; and the characters of these are pretty well defined, though it is not always easy to adapt the species to them. These subgenera are *Calocephalus*, *Stenorhynchus*, *Pelagius*, *Stenmatopus*, *Macrorhinus*, *Arctocephalus* and *Platyrrhynchus*.

CALOCEPHALUS. These have the cheek teeth with one large point in the middle of the crown, with one small one in advance of it, and two still smaller in the rear. The cranium is enlarged and rounded at the sides, and flat on the top, and only has a few rugosities in place of an occipital crest. The teeth are, in the upper jaw, three, four or six incisors, two canines, and ten cheek teeth, or five on each side, and in the lower jaw, four incisors, two canines, and two cheek teeth. Almost the whole of this group are inhabitants of the European seas, and the north part of the Atlantic, and the higher the latitude they are the more numerous. Jan Mayen and the other small islands near the polar sea literally swarm with them, and in the season ship-loads of them are caught in a very short time. The species of this section differ considerably from each other in appearance, but there is much similarity in the habits of the whole of them. The membranous sides of their feet are not extended beyond the points of the toes on the hind feet, and not so far on the fore ones. The toes gradually diminish in length to the inner one, and the outer ones on the hind feet are considerably larger than the others. From this, and also from the position of these feet, and their being of the same length as the tail, properly so called, they have the same

appearance as if all the three formed a broad swimming tail with its action upwards and downwards in the vertical plane. And, as a swimming apparatus the three have more varied motion than if they altogether formed one lobe. As each of the three parts has its separate articulation of bones and apparel of muscles, it can of course move independently of the others, and yet all the three can act in concert whenever the necessity of the animal requires such a motion. From this compound structure of their principal swimming apparatus, the seals have far more command of themselves in the water than the fishes or the *Cetacea*, in both of which the swimming organ, though differently formed in the different species, is single. In merely forward motion, the advantages of the compound apparatus are not felt; and, on a stretch, both fishes and *Cetacea* can swim faster than seals; but the seals can sport about in all directions in the water in a manner which no fish or whale can; for motion in every possible direction appears to be equally easy to them.

Their eye, which appears to be the organ of sense upon which they have their chief dependence when in the water, is adapted to this varied power of motion. There are some peculiar modifications in the general structure of the eye, which we can better explain when we come to speak of the organisation of the family generally; but we may mention that there is great muscular power in the iris of the eye; that the pupil expands to a broad disc when the light is very faint, and that it contracts toward a vertical line, as in the eye of the cat, when the light falls strongly upon it. From this structure in action, we may suppose that the seals chiefly ascend or descend upon the fishes that form their subsistence. All this section of the family, and they are the only ones of the manners of which we know almost any thing, are very sagacious animals, cautious in case of danger, but easily tamed, and capable of playfulness and attachment, which is inferior only to that of the dog.

STENORHYNCHUS. This section are distinguished by the great elongation and the slenderness of the muzzle, which is the foundation of the name. Their cheek teeth have one prominent point in the middle of a conical form and curved backwards, and there is a smaller point in advance of this, and another in the rear, which are also rounded in these sections, and separated from the others by notches so deep that, seen sideways, each has the appearance of being three separate teeth. These teeth have only single roots, the claws on the toes are very small, and altogether the animals have a much more aquatic air about them than the common seal.

PELAGIUS. This division have the muzzle elongated, but very much enlarged toward the extremity, and the profile of the forehead is very much arched. The upper incisive teeth have furrows or grooves across their crowns, but the under ones are simple. The cheek teeth are thick and conical, with only very small tubercles in front and rear of the main point of the teeth. The claws on the hind feet are sometimes altogether wanting. They have no external concha to the ear; and, as is the case with the common seal, the females have four mammae on the belly.

STEMMATOPUS. Only one species is known as belonging to this division of the family, the mitted seal or crested seal of authors. Its most remarkable

external character is a membranous appendage to the upper part of the head, which is erectile at the pleasure of the animal. The cheek teeth are flat and broad, and have only a single root to each. They enter but a little way into the gums, and have their crowns striated rather than formed into tubercles. Their brain is large and well developed; they have no external ears; their muzzle is straight and blunt at the extremity; and their tongues, like those of the common seals, are short and cleft at the points.

MACRORHINUS. This section, like the preceding one, differs much from the common seal, especially in the teeth. They have the fore teeth conical and inclined backwards in the same way as the canines, only they are smaller in size. The roots of the cheek teeth are simple, and much broader than the crowns, which make them have something the appearance of nipples projecting from the central part of the root. Some of the species are the sea elephants of authors.

ARCTOCEPHALUS. These, as the name implies, have the head formed something like that of a bear, and they have on this account been called sea-bears; but the name is improper, as the animals have nothing in common with bears properly so called, whether of the sea or of the land. They have the head flattened, the muzzle narrowed, the four middle incisors of the upper jaw divided by a deep furrow in the top, and the under ones with a sort of ridge in the front and the rear. The cheek teeth have single roots, upon which the crowns appear only as tubercles on the tops of the roots; of these there are three, the middle are the largest, and the others very small. The fore legs are placed far backwards: the webs of the hind feet are longer than the toes, and terminate in five lobes. Only one species is known.

PLATYRHYNCHUS. These have the head much arched and elevated, and the muzzle flattened. Their incisive teeth are pointed, and the hinder tubercle upon the cheek teeth is wanting. In other respects they very much resemble the members of the preceding genus. They have been called sea-lions, which is of course as incorrect as the names of land animals which have been given to some of the others.

Such are the subdivisions of the seals according to the careful observations made upon them by F. Cuvier, but so little is known of some of the species, that no arrangement can be any thing like perfect. We shall now proceed to say something of the general structure.

The seal family occupy so very peculiar a place in the system of nature and occur in such numbers, that a knowledge of their structure becomes a very desirable, and indeed an indispensable, matter. In respect of their locality and their habits, they are neither sea animals nor land animals; for they are equally fitted for making both their habitation. They are not amphibia in the full sense of the word, that is, they are not capable of carrying on all the functions of life equally in the land and the sea, in the air and in the water. If we take this view of them, they may be said to be incapable of living wholly in either. They must breathe the free air, as is the case with all animals which have lungs; and although it is not necessary that they should come to the land to breathe, they must rise to the surface of the water always when they perform that operation. On the other hand, they are quite incapable of finding their food on the land, or in the air, because they are so completely and exclusively formed for swimming that

they cannot so move upon the land as to be able to catch a single article of food there.

The other flesh-eating mammalia which they resemble the most are the otters ; but still there are great differences between them. The otters are truly and properly land animals, which hunt in the water for the principal part of their food, but they always bring it to the land to be eaten ; and upon emergency they can find the whole of their food upon the land, and are in the habitual practice of so finding part of it. The seals, on the other hand, always eat their food in the water, as well as catch it there ; and though they come on land occasionally, they make no nests, burrows, or other dwellings upon it, as is done by all animals which claim the land as their habitual and proper home. The females suckle their young upon land, and it is understood that, generally at least, they bring them forth in the caves just by the margin of the waters ; but even there the bare rock or beach is the only nest which they require.

In order to fit them for their aquatic mode of life, they can do with less frequent breathing than any of the other mammalia, the whales themselves perhaps not excepted. For a long time it was supposed, and the popularity of Buffon's writings tended not a little to extend and prolong the erroneous supposition, that in the seals the *foramen ovale*, or internal communication between the chambers of the heart, which is open in the fœtus of most if not all of the mammalia, remained open through life ; and that, by means of this foramen, they could carry on the circulation of the blood without breathing. There were two mistakes in this matter, one of them structural and the other physiological, and both of rather a curious nature. In the first place, the foramen does not remain open, and in the second place, though it did, that would not enable the circulation to go on in a healthful manner. We can draw no analogy from the *fœtus in utero*, as to the economy of the animal after it is born and thrown wholly upon the action of its own system. The blood of the fœtus may circulate any way, because the fœtus does not aerate its own blood. That operation is performed before the placental nourishment enters the body of the fœtus ; and thus, though there is a circulation in the systematic arteries and veins, there is none in the pulmonic. But when the umbilical cord is divided, and the animal has to find air for its own blood, the case is very different ; and though blood were to pass from artery to vein, or from vein to artery through the foramen ovale, that would no more alter its character than passing in or out at a door alters the character of a man. Cuvier is of opinion that a pretty large venous cavity, which is found in the liver of the seals, enables them to continue longer without breathing ; and though we know not in which way the blood may be treasured up there, yet it is not impossible that the portion of the blood which is unfit for the purposes of life, until the air has acted upon it, may be stored up in this. At all events, the seals can remain much longer under water without coming up to breathe than one would readily suppose to be the case with animals of common energy, if there were not some peculiar apparatus or modification in their circulation. But what this modification may be is another matter, and one upon which it is by no means easy to get direct information : only we may rest assured that it is not because the foramen ovale remains open.

True to its compound habits, the seal is an animal of compound structure, or, at all events, of compound appearance. The form of its body still retains much of that of the land animal, while the shape and the organs of motion adapt it for the water. The covering of the body is also that of a land animal, and not of a fish, or even of a whale. All the seals are covered with hair ; sometimes the greater part of it is hard or bristly, but laid smoothly on the skin, and having a polished or shining appearance. This hair is, generally speaking, more or less flattened, and tapering to the point. It gets wetted, as is proved by the fact of the difference of colour when immediately out of the water, and after being some time on land ; but it has no tendency to get in any way twined or matted by the water, neither does it take such a hold on the water, as in any way to impede the motion of the animal. Besides this, many of the seals have the body under the long and shining hair covered with very close, soft, and delicate fur, which is often used for ornamental purposes, and has this advantage over the fur of land animals, that it is much less injured by getting wet.

The arms and fore-arms of the seal are very short, and wholly concealed under the skin of the shoulder and breast ; and the fingers, which are five in number, are united by membrane into a sort of paw or paddle, which is of considerable use to the animal in swimming, and their chief organ of motion when they shuffle along upon land. The hind legs are still more concealed, and have less of independent motion than the fore ones ; but the toes are more webbed, and they are altogether more efficient in swimming. The motion of the seal along the beach is, in fact, a swimming motion ; the paws strike backwards, instead of being planted like those of a walking animal. Thus, when the seal moves along a stony beach, the backward stroke of the paws often throws the stones to some distance behind ; and this has given rise to the vulgar notion that the seal retreats like a Parthian, discharging its missiles on the enemy. Whatever may have been the fact in the case of the Parthians, this throwing of stones and gravel behind it is not intentional on the part of the seal. Indeed it is a disadvantage ; for all the effort which is spent in throwing the stones is lost to the animal in making its way ; and if one wishes to capture a seal upon land, stony and shingly places are those in which the attempt is most likely to prove successful. It is but very seldom, however, that a seal can be taken in this manner ; for it is so vigilant, and generally so near the water, that it is launched before one can come up with it. The adventure of Captain Macintyre and the *Phoca* in Scott's "Antiquary," the mention of which was so annoying to the pride of the soldier, is extremely well told ; but as a real occurrence, is not the most likely,—though, if the passage of a seal to the water is interrupted in the way there represented, there is little doubt that it would show fight, and readily wrench a stick out of the hand of its assailant, and make off with it to the water, as there stated.

The skeleton of the seal resembles that of the land mammalia much more than their external shape would lead us to suppose. The size of the brain demands a corresponding capacity of the cranium. In the spinal column, the spinous processes are much shorter than they are in land mammalia, as much less motion in the parts of the spine is required than in

animals which have much action in walking, running, and leaping. The ribs are fifteen on each side, ten true ones, and five false. The sternum is made up of eight pieces of bone nearly straight, and the last one longer than any of the others. The neck of course has the normal number of seven vertebræ; and there are fifteen dorsal ones for the articulation of the ribs. There are five lumbar vertebræ, with very short processes, four sacral ones, and twelve caudal. The pelvis is long and straight, and the *os pubis* is articulated in nearly the same manner as in man. There are no clavicles, so that the animals have no cross motion of the fore paws, and cannot use them as claspers in the way that they are used by the whale. The head of the humerus is well formed, and that bone itself is longer than the corresponding bone of the posterior extremity. The bones of the fore-arm are very dark, and the carpus and tarsus consist each of seven bones.

Of the senses of the seals, it is difficult to speak with much precision. Their sight is probably the most acute of the whole, and the one upon which they have their chief dependence in the finding of their food. On land they are, as we have already said, quick of hearing; but how and to what extent that sense may serve them under the water it is not easy to say; but from the structure of those parts which are considered as the organs of hearing in fishes, it is difficult to draw any conclusion as to how the ear of the seal, being as it is, a quick ear on land, may be useful to it when under water. We must, however, just notice the organs.

In respect of the sense which is called touch, and which appears to be composed of the sensitiveness of the surface of the body and of the muscular sense jointly, the seals must be dull. None of their extremities, or indeed any part of their skin, can be looked upon as the peculiar seat of such a sense; and sensibility of the skin would be a very inconvenient faculty in animals which are exposed to so great alternations of temperature as the seals experience in their ordinary habits. In their transitions from water to land and the reverse, they do not appear to feel the least uneasiness; and in the polar seas they do not appear to be in the slightest degree affected by the utmost rigour of the atmosphere, or the most rapid passage from one extreme of temperature to another. It does not appear that the hairs upon them are, in the general covering of the body, possessed of the same degree of sensibility as the hairs of land mammalia. Many naturalists have, however, come to different conclusions respecting the long bristles, or whiskers, which are near the mouth. These are, in some of the species, jointed, or formed with nodosities, something resembling those of the antennæ of some beetles. They have their roots in a sort of cylindrical capsule of horny consistency at the bottom, and meeting there with some small vessels connected with the muscles, and also with a fine membrane, which lines the whole of their internal surface; and the opinion is, that the bristles are, through the medium of this, a sort of organs of touch. These bulbous roots of the bristles, especially in the fine membrane with which they are lined, are closely connected with many ramifications of the second principal branch of the fifth pair of nerves; and this is another reason, and rather a powerful one, for concluding that they are organs of touch: the more so that it is pretty well ascertained that the whiskers of all land animals

which have such appendages in the form of bristles are of this description. But still, when the seals are in the water we cannot suppose that the sensations communicated by means of their bristles can be very acute.

The tongue of the seal is much better adapted for being an organ of taste. In the common seal it is about three inches long, and one inch and three quarters broad at the base. The *os hyoides*, or base of the tongue, is well formed, and amply supplied with muscles. In that species, and also in most of the others, it is cleft at the point, furrowed in the posterior part, and beset with papillæ of different sizes, which are understood to be the proper organs of taste.

The sense of smelling is much less perfect than in the land carnivora; and to have given this sense in any very high degree would have been giving a power which would have been of comparatively little use to the animals in that part of their personal economy in which alone senses are required, namely, the finding of their food. The nostrils are also shut when the seal is in the water, and there are two rather powerful muscles which work them; the one has its origin in the upper jaw-bone and the bone of the nose, and, proceeding obliquely downwards, is inserted in the "wing," or external and flexible lobe of the nostril. When it contracts, it of course distends the opening of the nostril; and when it relaxes, it allows that to be closed, so as completely to exclude the water. The other muscle, which is considerably thicker and stronger than this one, has its origin in the upper jaw-bone, near the alveole of the teeth; it passes along the substance of the upper lip, forming a plexus, in which the bulbs of the hairs of the whiskers are included, and then it is inserted on the inner surface of the wing of the nostril: so that, when it contracts, the nostril is closed with considerable force. It is often said in the books that there is a valve for closing the nostril of the seal, but there is no valve save the flexible edge of the nostril itself, which is worked by its muscles in the manner that we have described.

Of the hearing of the seals we have already spoken. Their internal ears have nothing very particular in their structure, and are tolerably well developed; and the presence or the absence of the external concha, though it of course modifies the hearing, and the distance at which the animal can hear, does not appear to be a matter of the very first importance.

Sight is, as we have said, obviously the leading sense in these animals, and therefore the eye merits more of our attention. It is an eye fitted for a double purpose or action; that is, it has habitually to be exercised in the water in the general economy of the animal; and it also has to act occasionally in the air. There is no eye which can be said to have, upon the whole, to perform both these offices so equally. The eyes of the whales, though no doubt in part fitted for seeing in the water, are very secondary organs in the economy of these animals, as they do not guide them to their ordinary prey, and cannot do so, from the particular situation which they have in the head. The eyes of the otters, also, are used in the water, but always at small depths, where there is abundance of light, and where any terrestrial, or rather aerial eye, could see perfectly well as long as its owner could remain below the water. The seals

have to use the eyes deep in the water, and when there is very little light, or indeed none, or next to none, as when the surface is very much roughened, or covered by ice with snow over it, which last must exclude the light. Yet the seals do not hibernate at those times, even in the long night of the arctic winter; for they are careful to keep breathing-holes in the ice, and, while an animal continues to breathe, it must also eat.

While the eyes of the whales are remarkably small for the size of the animals, those of the seals are very large. In this they follow a very general law among animals, whatever may be the element in which they live. If they depend chiefly upon the eye, and especially if they are feeders in the night, or in places to which little light can come, we invariably find that they have the eyes very large. This is the case with owls, and other nocturnal birds, and also with those nocturnal mammalia which find their food chiefly by sight. It holds even in the sea. The surface-fishes usually have the eyes small; and they get gradually larger and larger, till, when we come to those which inhabit the deeps, and yet are active, feeding upon other fishes, their eyes are very large, of which we have an example in the *stargazers*. It must not be understood that we mean to say that the large eye has the sense of vision in greater perfection than the small eye, for sensation is not a quality of matter, but a function of life, and therefore the acuteness of it has nothing to do with the size of an organ; and we find that, in equal lights, if they be strong ones, the small eye has the better of the large one, especially in the power of enduring a continued exposure to the light. But in faint lights the large eye has a greater field of view, and thus finds the object more readily than a small one does, and it also admits more light. The large eyes of the seals, therefore, are well adapted to the imperfect light in which they have to find their food.

The eyes are placed very near to each other, and thus they indicate that the animals follow their prey upon the forward view, as is done by the nocturnal quadrumana, which also have the eyes very near to each other. The form of the eye-ball is nearly spherical, the vertical diameter in the common seal being an inch and a half, and the horizontal diameter an inch and a third. This is in accordance with the form and action of the pupil, which closes to a vertical line. The sclerotic coat of the eye is composed of a fibro-cartilaginous membrane of considerable thickness, very hard and firm in the fore part round the cornea of the eye, and also in the posterior portion, but soft and rather flexible in the part intermediate between them. The structure of the coat, which may be considered as forming the basis of the eye, is peculiar; Blumenbach and some others have supposed, and certainly with much probability of being correct, that the flexibility of the central zone of the sclerotic admits of an adjustment of the focus of the eye, by means of which the animal can see equally well in the water and in the air. The cornea of the eye is flat, like those of the eyes of most aquatic animals, there being less distinction of light from a flat cornea than from a convex one of the same surface. This cornea is about three quarters of an inch in diameter, and thicker at the sides than in the middle. The crystalline lens is spherical, like that of fishes, and about half an inch in diameter. All the parts of the eye are, indeed, very well formed, and

the muscles with which it is supplied are of considerable power. The lachrymal gland is very small, as the eye does not require to be lubricated with the secretion of this gland when the seal is in the water. From its equal adaptation to the air and the water, the eye of the seal is an important one by means of which to study the physiology of eyes generally, but our limits will not permit us to pursue it farther. We shall therefore cast just a passing glance on the geographical distribution of these most curious animals.

There is no sea on the surface of the globe in which seals are not to be met with,—not in the breadth of the great oceans indeed between the shores, though they are capable of taking journeys of considerable length. They are no where so abundant as on the shores of the dreary lands in the high latitudes, and near the margins of the ice; and in the north they form an important article in the domestic economy of the inhabitants of those inhospitable climates. In the equatorial seas the seals are solitary, or seen at the most in pairs. In the temperate latitudes they assemble in groups, but not in very large numbers; but in the high latitudes of both the north and the south, the herds of them are so numerous, beyond all counting, that the most active fishing can hardly have any effect in thinning their numbers. Though they are less known in the high latitudes of the southern hemisphere than in those of the northern, it is probable that, taking all the longitudes into account, they are upon the whole more numerous, as they have the complete range of the parallel, which is not the case in any latitude of the north. Those of the three great divisions of the sea are chiefly different from each other, and they have been employed as the basis of a popular mode of division, which has the advantage of connecting the species with their habitats, without any formal description. There are the seals of the North Atlantic, the seals of the North Pacific, and the seals of the South Seas; among which latter there are of course no longitudinal distinctions, as there are no lands to separate the seas from each other, and give them and their productions different characters, as is the case with the North Atlantic and the North Pacific, where the great current in the north parting the former, and the comparatively small one in the latter, give quite a different character, and bring the arctic winter farther to the south in the Pacific than in the Atlantic.

In all the seas in which they are found, the seals frequent the shores only at a certain season of the year, and appear to disperse themselves more generally over the waters during the remaining portion of it, which is usually much longer than that in which they throng to the shores. Those of the south resort chiefly to the dreary and inhospitable isles which lie off the southern extremity of the American continent, though they also come in considerable numbers to the shore, especially the south-west, which is much broken by inlets of water and little isles with channels between. The south of Africa is rather warm for their coming to it in any considerable numbers; but they resort in formidable array to the south part of Australia, and especially to Bass's Strait, where the islands are favourable for their basking, and fish are abundant for their food. In the northern seas they resort to the shores generally in the high latitudes; but there also they prefer the islands to the mainland. Among the Aleutian islands, and in all the

basin which lies between these islands and Behring's Strait, the seals assemble in vast multitudes; while those of the North Atlantic seek both the shores of the northern islands and the borders of the ice.

When they resort to the land there are some differences of habit among them, especially among those of the south. Some resort to the open sandy beaches; others to the rocks which are surrounded by the water, and others again to the coarse herbage which often extends to the margin of the water. Fishes are understood to form the principal food of all the species; but they also eat polypi and other floating animals, and even sea-birds, such as terns, petrels, and the smaller gulls, which are usually very plentiful in the great haunts of the seals, and resort to them for nearly the same purpose as the seals do; only they eat the smaller fishes, while the seals prefer the larger ones.

Seals are not easily killed by means of cutting instruments; for though the wounds bleed copiously, the labour of killing them in this way is great, unless some of the more vital parts are wounded. But the great development of the brain renders them much more vulnerable in the head than in any other part; and the quickest way of despatching them is by beating them on the head with heavy clubs. This is extensively done by the seal-fishers at Jan Mayen, where the animals are found in such numbers, that the men can knock them on the head till they are absolutely wearied with the slaughter; and in the best time of the season they very speedily fill a boat, or even a ship with a valuable cargo. The seal-fishing commences earlier in the season than the whale-fishing; and when the fishing vessels that resort to "Old Greenland," that is, to the vicinity of Spitzbergen, arrive too early, they bear away to Jan Mayen for the seal-fishing. Sometimes the "seal club" is exercised to no small advantage on the caverned shores in the north of Britain. These caves penetrate to such distances into the rock, that they are quite dark for a considerable way. The seals resort there to take their siesta; and the people watch their time, enter the cave with torches and clubs, and the seals, alarmed and nearly blinded by the glare of the torches, become an easy prey. There is of course a great deal of scrambling on these occasions; men and seals rolling over each other on the slippery stones; and sometimes a seal will wrest a club from the owner, and bear it off in triumph to the water.

In early times, when navigation consisted of little more than coasting and crossing the narrow seas, the seals, as well as the *Cetacea*, were far more numerous than they are at present; and their numbers came into lower latitudes. But the fishery which was carried on at first by the Dutch, and latterly by the British and the Anglo-Americans, has greatly thinned their numbers, and confined them within much narrower bounds than they previously were. Any one will readily understand that seals are much more likely to have their numbers thinned in this way than fishes; because they produce only one or two young ones at a time, while the fishes produce thousands or even millions. What man can capture by all his arts of fair fishing in the sea is not missed in the multitude of his finny prey; but it must tell in the case of the seals. Seals are also far more wary and sagacious animals than fishes; and thus, when they

are greatly molested on one ground, they are very apt to shift to another. Hence those of the North Atlantic became so much thinned, that adventurers, chiefly English or American, have sought for them in all the inhospitable regions of the south. Those fishing expeditions to the south, having originated in a more enlightened and liberal age than those of the north, have tended to increase our knowledge of those remote seas. These discoveries indeed have done little more than show that there really is nothing to be discovered except a few wild rocks covered with snow for great part of the year; and affording resting places for seals and sea-birds only. But this is something, as it prevents waste of time, which would otherwise be occasioned in seeking that which is not to be found. Mr. Weddell, of the brig *Jane* of Leith, carried discovery into a higher latitude than it had previously reached in those seas. On the 20th of February, in 1823, he reached the latitude of $74^{\circ} 15'$, which is higher by two hundred miles than any other navigator has penetrated into the antarctic ice. No land, however was seen in that longitude (about 35° west), to the southward of New Georgia, which is a distance on the meridian of about 1500 miles. As the seals are among the rocks, or in the more shallow waters, small vessels answer best for this fishery; and in all coasting fisheries, or other operations in the water along-shore, small trim vessels are always the safest and the most manageable. The complement of men is about twenty-four; and the proper outfit of an expedition costs from 4000*l.* to 5000*l.* The vessels are strongly timbered and double planked. The rigging of the vessels is also very simple, but very substantial. They have generally a smaller vessel, about forty tons burden, which can be stationed near the shore as a general rendezvous for the fishing-boats, which are usually six in number, and constructed in the same manner as whale-boats. A good deal of experience and skill are required in choosing the ground; and when the proper spot has been selected, the vessel is moored in a safe place, and the apparatus for boiling the oil erected on the beach. The small vessel thus acts the part of a tender between the boats and the station. The seals are chiefly surprised and knocked on the head while on the rocks; and when this is over for the time, they are skinned and cut in pieces, which are stowed away in the small vessel. A load of the small vessel consists of about two hundred seals, which yield from eighty to a hundred barrels of oil. When the vessel arrives at the part where the boiling is carried on, the cargo is delivered and boiled, the flesh of the seals after the oil is extracted serving for fuel.

This fishing is one of great hardship, and often of great peril. The ships are sometimes out for three years, and all the time in a sea which is any thing but *Pacific*, while they are often at the distance of thousands of miles from any supply or assistance. Still, when successful, it is profitable, both for the oil and for the skins. The species in most esteem for oil are the long-nosed ones, called sea-elephants by the fishers among the earless seals, and the maned seal or sea-horse among those which have external ears. But they differ much with the latitudes and also with the longitudes of the places at which they are taken. Those most in request for their fur are those which are popularly called sea-bears; but there are many species which get the name of fur-seals. Seal oil is accounted purer and better than that of

the *Cetacea*, unless when obtained from the spermaceti, or half-crystallised stearine; and the great markets for it are Europe and America. The three principal kinds of sea oil are whale oil, seal oil, and cod oil, the last obtained from the livers of the fish, and preferable to every other for the dressing of leather. We believe that, by some absurd custom-house law, whale oil is the only one of the three which is called *fish* oil, although it is not fish oil; and that, in some places at least, the others escape the annoyance, both of the protections and prohibitions which affect this. A good many of the skins are also brought to Europe and America, but the grand market for them and for all furs is China. The fur seals are also found upon the shores of the southern lands in May, June, July, and part of August; and they return again in November and December, at which time the females produce their young, which they suckle for about nine months. It is generally said that the seals swallow pebbles as a sort of ballast before they go to sea, and discharge them again by the mouth when they come on land; but the story is not in very good keeping with what we observe in nature, where our opportunities of observing are more favourable than they are in the case of the seals.

On the eastern coasts of Siberia, both to the northward of the Aleutian Islands, and between these islands and the Kurile chain, seals are exceedingly abundant; and their manners might be more easily studied in those seas than in any others. They there ascend the rivers to a very considerable distance after the fishes; and in some of our own rivers, a stray seal sometimes makes its appearance ten or twelve miles above the brackish water; but this is so rare, that the animal is shown as a curiosity, and its appearance is supposed to be of an ominous character. The pairing time in the North Pacific is about April, and the females have only one young at a birth. The milk of the seals is of very superior quality, and the women of the dreary shores of Kamtschatka and the neighbouring lands procure it as a medicine for their children. They cannot be regarded as the flocks and herds belonging in property to the people of these inhospitable lands; but they answer many very useful purposes. The skins serve for clothing, for boats, for sails, for tents, and for various other articles; the fat is made into candles, or burned in lamps; the flesh is dried and smoked for winter provisions, and the recent flesh is cooked for the table; that of the young in particular is said to be very good. Notwithstanding all these uses, the seals cost the people nothing but the capture, which is an easy matter in places where the animals are numerous. There is also no doubt that they could be brought into a state of complete domestication, so that their usefulness would be greatly extended; and where land is ill adapted for flocks, the sea might be made a sort of substitute.

We shall now notice a few of the principal species; first, of the seals properly so called, *Phocæ*; and then of the eared seals, *Otaria*.

PHOCÆ. The leading characters are: No external conchæ to the ears; the fore teeth with single trenchant points, and the cheek teeth always with more than one; the hind feet with pointed claws placed on the margin of the web by which the toes are united. As the specific distinctions are not very clear, it may, perhaps, be better to take these in the three geographical divisions:—First, seals of the

North Atlantic; second, of the North Pacific; and third, of the South Sea.

SEALS OF THE NORTH ATLANTIC. These are the best known; but it is probable that, even among them, coloured varieties have been described as species, and species have been overlooked.

THE COMMON SEAL (*Phoca vitulina*) must be considered as the typical one of the genus. It is found upon the shores of all the colder places of Europe; but it is most abundant in the currents and narrow waters, as we have mentioned generally of the family. It is usually about five or six feet in length, but some specimens are more than this. The colour is yellowish grey, mottled over with dusky spots; but it is not constant. The skin, and the short hair upon it, are yellowish; and the long hairs have a grey tint and shining surface. When the animal rises immediately out of the water, these hairs, which are flattened, are laid close to the skin, and completely conceal it; but as they dry they stand more detached from the skin and from each other, which varies the change of colour to a yellowish tint, on all parts from the ridge of the back where the hairs are closest. When they get very old, the hairs turn very pale grey, and in some cases almost white. Some individuals are also much darker than others, and almost black when they first come out of the water; and there are very great differences in the size and number of the spots. In short, there is no dependence in colour or any part of the description of these animals.

Common seals, though these may perhaps be classed among animals which are familiar in their manners, are yet very watchful and wary. When they are at rest on the banks, they very frequently raise up their heads to see if there is any chance of danger. In the estuaries, where there are banks in the mid channel dry at low water, though still surrounded, they take up their station there in great numbers; and they appear to be more suspicious of a boat than of a ship: for we have seen them remain quite undisturbed while a vessel sailed by close to the bank; and yet shuffle very speedily into the water if a small race-boat came within the same distance. Even in the case of the boat, they appear to make a distinction between one which is simply passing by, and one which is making for the bank on which they are reposing. They are also very expert at getting at their prey, and in escaping from any entanglement into which they may get in the pursuit of it. When stake-nets for the capture of salmon were allowed to be erected in the estuaries, the seals often found their way into the labyrinths of the nets, enjoyed a comfortable meal of salmon there, and got out again in perfect safety; and when they get enclosed into nets from which they cannot find a passage, they creep through below, or scramble over the top with much adroitness. They appear to be more partial to salmon than to any other fish, and in some places they follow them into the lakes, when these are not at any great distance from the sea; and to accomplish this they will stem the current of a very rapid river.

On the British shores they usually bring forth their young in June, which are either one or two in number, but never more. The places where this happens are the most secluded caves and holes in the rocks, in which the young remain for some time, the mother going into the water to find their own food, and returning to the cave to feed their young. They

have not the same power of clasping with the fore paws which is possessed by the whales. The young are often killed in the caves, and their skins are held in some estimation on account of the gloss of the fur. In former times both old and young were eaten; but the flesh, especially that of the old ones, is coarse and dark coloured, and the flavour of it is rank and oily. There is perhaps no stronger proof of the great superiority of the staple animal food of the present times, over that with which the people of this country were formerly supplied, than the disuse of seals, porpoises, and other sea animals, for the table. In those days the sturgeon was held in such estimation that it was considered as a royal fish, and any stray one which now occurs gets a little credit probably for the high place which it once occupied; but as food, the best that can be said of it is that it is tolerable, which is more than can be said of the mature seal. At present, seals are valued only for the oil and the skin; and as there are but few places on the British coasts where they occur in such numbers as to render the capture of them a profitable occupation, they are left in quiet possession of the sea and the banks, except in some of the remote places, where they are more numerous, and where human labour is of less value. In most places the capture of them has fallen off, compared with what it was in former times; and yet it does not appear that there has been any increase of the numbers, but rather the reverse. Besides the modes of capture, to which we have alluded when speaking of the family generally, dogs are, or at least once were, in some places, trained to catch seals.

Seals are much more easily tamed than almost any other of the wild mammalia that are found in the British islands; and if they are taken young, and tolerably well used, they soon learn to know their keepers, and evince nearly the same attachment to them as dogs do. Of course, in order to be properly in their element, they must have access to the water, which is essential to their comfort, though not to their mere existence. They cannot of course accompany their masters on land journeys, but they are very constant on aquatic ones, and the watchfulness which is so apparent in them in a state of wild nature is capable of being turned to good account in domestication. F. Cuvier, whose observation of animals in the French Menagerie was equally close and accurate, paid considerable attention to a pair of live seals which were in that collection. They were very young, not exceeding three feet in length, from which circumstance, by the way, some of the French describers have set down three feet as the average length, as if seals had no right to be bigger any where than they were in the menagerie. From the observation of these, there seemed reason to conclude that a fluid is secreted somewhere about the head of the seal, which lubricates the body when the animal is in the water, in some such way as the bodies of fishes are lubricated by the mucous secretion. These animals did not show the slightest apprehension at the sight of the company that visited their abode, though they shuffled out of the way pretty quickly when there appeared to be danger that they should be trampled upon. The sounds which they uttered were very feeble barking, and when they were annoyed they made a sort of hissing noise, like that of a cat when suddenly offended. They never offered to bite, but they sometimes menaced with the paw;

and when they contended about their food, which they did sometimes, they used the paws, not in a very warlike manner, but merely to push each other away. These seals were, however, rather too far removed from their own natural element and economy for enabling one to form a correct estimate of the character of the species.

One seal, which had been captured young, and was kept for a considerable time by some artillerymen on one of the small islets in the Firth of Forth, would have afforded a better illustration if its history had been fully recorded. It was during the late war, when the rumoured invasion had caused the construction of little forts and martello towers on so many places of the coast, and Inch Colm was, we believe, the islet; the bombardier corps of men had little to do in their lonely abode; and so they tamed a seal, till it showed a very strong attachment to them. It went often to the water, but never showed the least disposition to go away. On the contrary, it made some demonstrations which had the appearance, on its part, of a wish that, as it was their companion on land, they should be its companions in the water. It used to snatch their canes out of their hands, and get into the water with them, where it displayed them to the owners with a good-natured air of triumph. If they made efforts to get at it and the cane, it would advance and retreat and play many tricks; and if they took no notice of it, it would bring the cane on shore, but be off again before they could get hold of it. If they threw any piece of stick into the sea, the seal was instantly after it in the same way as a water spaniel; and in short, all its tricks very much resembled those of the more playful varieties of dogs.

It did not sleep on the rocks, but in the little barrack which had been erected for the men; and during the day it was very fond of getting into their beds. Its entrance into them was effected with tolerable expedition; but to descend was a more difficult matter, as it was apt to tumble, and at last was killed by one of these falls. It is apparent to any one who looks at a seal, or a good figure of one, that the animal can climb much better than it can descend; and that, though it can shuffle rapidly down a slope, yet it cannot descend perpendicularly from a height in any other way than by throwing itself down; and the fall is dangerous, unless it be into water, which is its usual landing in a state of nature.

When the party came to Leith in their boat for a supply of provisions or stores, the seal was on the *qui vive*; and after a few trips it seemed to understand, when the boat was getting in order, what was to be the result, for it capered about the boat apparently very much pleased, and when the boat rowed off, it swam along with it; but, in order to show that it was the swifter of the two, it used to take a turn round the boat now and then, and come to the gunwale as if to show that it had performed a feat. When they landed at the pier and made the boat fast, the seal took its station in it, and kept intruders at bay until the men returned. It was altogether a very interesting creature, and, of course, its fatal accident was much regretted by its masters.

There seems little doubt that with proper attention, and not a great deal of it, the seal might be domesticated by the people who live on the shores where it is common. From the readiness with which the one alluded to brought sticks out of the water, there is little doubt that they might be trained to catch fish.

The otter has been so trained; and the seal is at least as intelligent as the otter, and it is an animal of much more gentle disposition. The milk of the females might also be used for domestic purposes; and, in short, it is highly probable that, by proper attention, a good deal might be made of the common seal.

THE GREAT SEAL (*P. barbata*) is the only other species which comes to the British shores; and only to the remote northern and western isles, where it is a straggler more than anything else. It is much larger than the common seal, being twelve feet in length, and sometimes more. They are said to be found in pairs only, and not in herds like the common ones. The hair is coarse, and of a blackish grey or brownish colour, but it does not appear to be more constant in this respect than it is in the common seal. The following description is from Ross's First Voyage to the North-east of America; but the specimen does not appear to have been full-grown:—"Length from the tip of the nose to the extremity of the tail eight feet; its circumference behind the fore flappers seven feet five inches; weight eight hundred and thirty pounds; fore flappers measured in length eleven inches, in breadth six inches; hind flappers in length sixteen inches, in breadth two feet when expanded; the claws on the former were black, horny, and curved, those on the latter long and straight; fingers five, middle ones longest in the fore flappers; the body covered with thick, coarse, short, dark grey hair; the eyes about the size of an ox's, furnished with a nictitant membrane, irides dark hazel; the pupil elliptic, perpendicular; no external ears; the auricular apertures placed about two inches behind the eyes; the upper lip broad, rounded, fleshy, divided into two lobes by a deep suleous division, which is black and naked; each lobe is provided with eight rows of strong white bristles, some pellucid, and curled at the ends; the lower lip thin, and pointed; tongue thick, pointed, and cleft; upper surface papillous; teeth, upper front six, truncate, small; tusks solitary, truncate; grinders three, the anterior one solitary; lower front four, imperfectly developed; tusks small and obtuse; grinders seven, the two posterior imperfectly lobed, the rest being small tuberosities, scarcely produced through the gum; the heart about the bulk of that of an ox, its texture strong; the foramen ovale obliterated (a point on which there is yet some discord among comparative anatomists). The aorta three inches in diameter, its coats two and a half lines in thickness; the calibre of the pulmonary artery nearly the same, the thickness of its coats one line; kidneys elliptic, lobes one hundred and fifty to one hundred and sixty; stomach filled with a greenish dark fluid; its inner coat lined with escharides one inch and a half long; they hold on with great tenacity, rendering it difficult to disturb them; the smaller intestines were inhabited thickly by *lenixæ*, from one foot to four feet in length." Such is the circumstantial description given of this specimen; but the descriptions of the seals of the high latitudes given by different writers vary so much, that it is difficult to reconcile them.

This species is also called the bearded seal, from the mustachios on the upper lip. The middle toe on the fore paws is very long, and the inner one very short. On the young ones the fur is much softer than on the adults, and that on the under parts is partially woolly. The hair falls off to such an extent that the very old ones are nearly naked; the colour also changes so much with age, that the species is

NAT. HIST.—VOL. III.

apt to be mistaken. Their chief abode is in the high latitudes near the polar ice; they come to land or to the margin of the ice very early, and in March or April the young are brought forth. One at a birth is understood to be the number, and they are often cradled on the floating ice. They are timid animals, and have not the watchfulness of the common seals. The Greenlanders esteem their flesh as an article of food and that of the young ones is said to resemble veal in colour, and not to be unpleasant in the taste. The people in the northern lands esteem them as being among the most valuable of all the seals.

GREENLAND SEAL (*P. Greenlandica*). This species is found in the same seas as the last mentioned one, only it never rambles so far to the south as to be met with on even the remotest of the British isles. It is subject to still greater variations of colour than the last-mentioned one, and therefore the accounts of it are, if possible, more confused. It attains the length of ten or eleven feet, though smaller ones are more frequently met with. The colour is most commonly yellowish-white, with the muzzle and forepart of the head black or dusky, and the sides marked with large irregular blotches of the same colour. It is very generally distributed in the high latitudes of the North Sea; but the White Sea appears to be the only sea decidedly European to which it resorts, and its visits there are only seasonal. In the more northerly seas it is found throughout the year, and eagerly sought after both for the oil that it affords and for its skin; but it has been so differently described by authors who have met with it of different ages, and also in the sexes, which vary from each other in many external appearances, that it seems to have been made not less than half a dozen of different species, and to have been called by a whole dozen of different names. Even the number of teeth appears to vary at different ages, so that there seems to be hardly any permanent character about it. The general colour of the adult is the yellowish-white which has been mentioned, with the anterior part of the head, and a patch on each flank, nearly or altogether meeting on the upper part, of a colour varying from blackish-grey to almost entirely black.

Greenland Seal.

These markings, whether they incline more to grey or to black, are always very intense in the colour, and contrast boldly with the ground upon which they are placed. On the flanks they appear to be made up of a congeries of spots, which completely run into each other in the centre of the patch, but which are

S S

nearly insulated at the borders. The young are more inclined to white all over, but with a shade of ash-colour, and numerous spots on the under part of the body. These spots are but faint in the young, and vanish altogether in the full-grown animal. The teeth also vary at different ages; but the law or the causes of their variation have not been made out. The pairing usually takes place in June, and the young are produced in the end of March or the beginning of April following; so that it is ascertained that in this species the period of gestation is nine months, which is probably the case in most of the others. The produce is one, or at least very rarely two. The food is understood to consist of fishes, crustacea, and of those floating animals which are met with in such numbers at places where there are currents in the sea.

THE HOODED OR CRESTED SEAL (*P. cristata*). This is another species about which there has been no small confusion. The most remarkable characteristic of it is the hood or crest, which is attached to the head, and capable of being not only erected, but of being extended so far as to cover over the muzzle. This singular appendage is, however, found in the mature males only, and is wholly wanting in the females and the young, which has led to the consideration of them as different species from the males. The young are entirely white; but in the old ones the feet and the muzzle are black, or, at all events, very deeply coloured. It is more plentiful toward the western parts of the Arctic Sea than toward the eastern, and arrives in very considerable numbers in Davis' Straits. The males are understood to be polygamous; and the females have only a single young one at a birth, which they are understood to drop on the ice about the month of April.

Many other seals have been mentioned by authors as inhabiting the Northern Ocean and the European seas; but it is probable that many, if not the whole of them, are only coloured or accidental varieties; and even if they are really species, so little is known of their manners, and they are so much alike, in as far as they are known, that there is no popular interest in them. There is, however, one species which requires notice as being the type of F. Cuvier's genus *Pelagius*, as being chiefly found in the Adriatic and the Greek Sea, and as being in all probability the *Phoca* of Aristotle and Pliny. This is

THE ADRIATIC SEAL (*P. monachus*), also called the hooded seal, the monk seal, the Mediterranean seal, and other names. It is rather a small species, grey, marked with yellowish on the upper part, and yellowish-white on the under. The whiskers are long and stiff; and the claws on the hind feet are merely rudimental. As is the case with the other seals, this species is subject to very considerable differences of colour.

2. SEALS OF THE NORTH PACIFIC.—The portion of that ocean which narrows toward Behring's Strait, has been already noticed as one of the great haunts of the seal tribe; but they have not been examined with much attention to specific differences. They are not confined to the extreme parts of the ocean, but are found along the coast of America, and about the islands till they range so far as to meet the seals of the south; but they are less numerous near the equator than in the high latitudes. We have already mentioned the advantages which the inhabitants of the islands and shores of that sea derive from the seals; but, with the exception of the Russians in Siberia,

there are not many fishers from the nations of the west that resort to a place so very remote. The names given to the seals, of which specimens have been obtained from these parts of the world, are all doubtful; and the principal distinctions among them are those of colour only. Those which have been met with in the extreme north are of a white colour, closely mottled over with small blackish spots; those which have been obtained from the Kurile Islands, which may be considered as the south of the polar portion of that sea, are exactly the reverse, or black covered over with white spots; and those of the Aleutian Islands are yellowish-white without any spots, and the young are said to be all over as white as snow. Notwithstanding these varieties of colour, it does not appear that there are any very marked specific differences.

3. SOUTH SEA SEALS.—The seals of this part of the ocean have a much wider range than those of the north, and several of them are of more ample size. The largest of them, and the one which is most widely distributed, is

THE LONG-NOSED SEAL (*P. proboscidea*), which is also called the sea elephant, and various other names. It is sometimes found thirty feet long, and eighteen in circumference at the thickest part. It is generally of a bluish-grey on the upper part, but it is also met with, though more rarely, of a brown colour. The canines in the lower jaw are large, strong, and considerably bent, but projecting outwards. The bristles of the mustachios are long and coarse, and twisted like a kind of screw; the eyes are large and prominent; the fore paws are large and strong, with only five rudimental claws on the posterior margin of each; the tail is very short, and only partially appears between the hind paws, which latter are broad and flat. The most singular character of this species is, however, the proboscis, which is peculiar to the male, and appears on it only in the pairing season. This is a cellular enlargement of the point of the nose, soft, and barely perceptible in ordinary states, but capable of being extended to the length of nearly a foot, by the power which the animal has of injecting blood into the cells. But though it has the position of a proboscis, it has none of the action, and can be looked upon in no other light than as a mere appendage, similar, in season at least, to those which are found on the heads of some gallinaceous birds, especially turkeys. The hair upon these animals is exceedingly coarse; and in some seasons they get exceedingly fat, and a single one, when in the best condition, will yield a butt of oil. They also contain a great quantity of blood.

They are found in all places of what are called the South Seas; but always in the greater numbers the higher the latitude. They are the principal seals that are met with on the coasts of New Holland and Van Diemen's Land, and on those of New Zealand; but in both situations it is on the south or polar shores that they are principally to be met with. The Falkland Isles, the New Orkney, and Shetland, and all the dreary isles near the southern ice, abound with them, and so do the numerous isles along the western shore of South America; but they are never as far to the north as the Isle of Juan Fernandez. They are represented as being migratory with the seasons, moving northward in the winter and southward in the summer, which are of course at the opposite times of the year to the same seasons in our hemisphere.

Their food consists in great part of the cephalopodous mollusca which float in such numbers in those seas; but they are also said to eat sea-weed, the *Laminaria gigantea*, or great sea-belt for instance—at all events, they form a sort of bed for their young with this weed upon the sandy shores. During the first four months of the year they are dispersed through the ocean, and not to be met with on the shores; and for the rest of the year they are alternately on the land and in the water. They are heavy, mild-tempered, and unsuspecting animals, by no means so watchful of danger as the seals which are to be found on our shores. They allow the fishers to come close to them on the rocks, and fell them on the head with clubs; and those which do get into the water, launch themselves so slowly, that they are generally killed by the men who wait for them in the boats. They have another resemblance to the gallinaceous birds, besides the seasonal appendage to the head. The males are polygamous, each one having a number of females in his train, forming a sort of marine seraglio; and when two males encounter each other at this season, a fierce battle of gallantry ensues, in which, as is usual among animals in such cases, the females desert the conquered, and join the train of the conqueror. The young are one or two at a birth, produced about July or August; and the females suckle them for two or three months. When they migrate it is usually in herds of from a hundred and fifty to two hundred, the pugnacious disposition of the males ceasing with the season of which it is more immediately characteristic. The interest which is attached to these animals for their oil, is nearly as great as that which was attached to the Greenland whale before its numbers were so thinned as they are now, or the animals driven so far into the polar ice as to render the fishing equally uncertain and dangerous.

Animals which have long seasonal migrations are seldom so liable to changes of colour as those which are more local; and hence it is probable that these large seals of the south do not vary so much as the seals in the north. Still there appear to be very considerable differences; and they probably have been called by various names—generally by those of sea-lions, sea-wolves, and others equally out of keeping with the true characters of the animals. But some members of the other genus, or subgenus, have also been called sea-lions.

THE LONG-NECKED SEAL (*P. Weddellii*). This is also an inhabitant of the South Sea, and a much more polar one in its locality than the preceding. It has hitherto been met with only in the high latitudes of the south, indiscriminately on the shores of the barren lands and the margin of the ice. In some respects it makes a slight approach to the eared seals; and it has a rudimental external concha to the ears; the body is round and very thick at the middle part, but it tapers to the head, which is small, and has the muzzle much pointed; the fore legs are short, and the hind ones are drawn nearer to each other, with five short lobes at the extremity; and the claws are very small or altogether wanting; the hair is short, shining, and laid flat to the skin; the colour pale grey on the upper part, sprinkled over with small whitish spots; and the under part of it is yellowish. It grows to the length of seven or eight feet. Very little is known of its manners, however, as it has not been met with except in the extreme latitudes near the ice; and resting upon that rather than the land. Its value to

the seal-fisher is far inferior to that of the great seal which is so widely distributed over the southern ocean; because the places in which it is found are much more hazardous, and the animal itself is smaller and less productive of oil. The native locality of this seal was not very well known until Weddell penetrated so far to the southward; and each of the specimens (of which, however, there were very few) had a separate name. It is probable that the one described by Sir Everard Home, in the Philosophical Transactions for 1822, and upon which F. Cuvier founded his genus *Stenorhyncus*, is identical with this one; in like manner as it is probable that all the sea-elephants which have been mentioned as found at different places, and differently named, are really identical with the one which we have described. The seals of the South Sea are, however, an intricate portion of Nature, and a long time will be required before they are properly understood.

OTARIA, or EARED SEALS.—The distinguishing characters of these which are the most essential to be borne in mind are: the possession of an external concha, which surrounds and covers the opening of the ear; the fore feet merely swimming paws, or fins without the slightest vestige of claws, and placed at the middle of the length of the body; the hind legs placed near to each other with strong straight claws, and their swimming lobes very much produced; the incisives trenchant, and the cheek-teeth strong and conical. They are often called bear-seals, or sea-bears; and they are the species the skins of which are in request as furs. They are found in all the three divisions of the sea to which we referred in speaking of the seals; but they are especially abundant in the South Sea; and there are either a number of species there, or they are prone to run into varieties.

1. NORTH ATLANTIC.—There is only one eared seal in this part of the world, and it is confined to the high latitudes, being rarely if ever found to the south of Greenland.

COMMON SEA-BEAR (*O. Furbicæ*, or rather *Groenlandica*). This species is small, and, with the exception of having external ears, it has as many points of resemblance to the earless seals as to the eared seals properly so called; and hence many naturalists have felt disposed to consider it as confined to the Pacific and the South Sea. It is not, we believe, met with upon any part of the coasts of Europe, or upon those of Spitzbergen or Nova Zembla, but rather in the western part of the Arctic Sea, and chiefly on the west of Greenland. The fur is of a brown colour, there is no mane on the neck, and the swimming flaps of the hind feet are very long. It is doubtful whether some of the species which are found in the North Pacific have not been mixed up in the descriptions which have been given of this one.

2. NORTH PACIFIC.—The eared seals are far more numerous here than they are in that part of the North Atlantic in which they occur; but it is doubtful whether they have not been to a certain extent confounded with those of the south. They are particularly called sea-lions or sea-bears, without much regard to the distinctions of species.

SEA LION (*O. Stelleri*). This species has obtained a number of names, being the sea lion of some and the sea bear of others, the only title that it has to either of these epithets being the mane upon the neck. It has indeed something of the voice of a lion, or at any rate it makes a loud and bellowing sound;

but it has none of the propensities of the savage king of brutes. It is met with along the whole west coast of America, though most abundantly toward the north. It grows to the length of eight or nine feet.

Sea Bear or Lion.

The colour of the fur is brown, and the mane consists of a band of frizzled hair down the middle of the neck, having no resemblance to the mane either of a lion or a horse. The head is of mean size, the ears are short, the muzzle also is short, and it turns up something like that of a pug-dog. It can climb to a very considerable height on the rocks, though its fore paws are very short. It is very abundant among the Aleutian Islands, by the natives of which its flesh is held in much estimation. It is a very timid and harmless animal, notwithstanding the mane and the roaring.

The males are partially polygamous, but they have seldom more than two or three females in their train. The period of gestation is nine months, and the young are produced in May or June. Notwithstanding the partiality of the Aleutians to the flesh of these animals, they have at all times a rank and disagreeable scent. Though they are found along the whole line of the west coast of America, they are yet to be regarded as properly animals of the North Pacific, and not of the South; for as one proceeds westward their numbers diminish, and they are not found higher than 56° of south latitude.

CALIFORNIAN EARED SEAL (*O. Californiana*). There is a little obscurity about this species. As described it is smaller than the former; covered with uniform smooth yellowish-brown fur, and with the mustachios small; the muzzle is very pointed; the fore paws are much larger than the hind ones, with five rudimental claws and enlarged membranes; the hind feet are slender, with three claws on the middle toes of each, and rudimental ones on the exterior and interior; there are five lancet-shaped lobes of membrane which extend nearly half a foot beyond the points of the claws; the tail is very short. The habits are wholly unknown.

SEA BEAR OF STELLER (*O. Krachennimikofsi*). This is the "sea cat" of the Russian, whose almost unpronounceable name it bears; and to whom we are indebted for a good deal both of real history and romance respecting the sea on the coast of Siberia. The length is eight or nine feet in the very largest specimens; and the muzzle is longer and the teeth more powerful than in the sea-lion. The old ones are blackish with

grey spots on the upper parts, and the young are bluish-grey. In the old ones the fur is grey at the points, and has altogether a bluish tinge; the feet are naked and black in the colour. They are found chiefly in the northern parts, where they shift their locality with the seasons. They collect in the greatest numbers toward the mouth of the rivers, so that the fishing for them is more on the continents than the interjacent islands, though they are also pretty abundant on these at some times of the year. They have a most offensive odour; but still they are sought with great eagerness for the sake of their fur. The fur of the undropped young, which is of a beautiful bluish-black, is the most esteemed; and the females are caught in vast numbers in order to procure it. The males are polygamous, each having ten, fifteen, or more, females in his train; and, as one might expect under such circumstances, the males fight desperate battles of gallantry. The females show very great attachment to their young; but it is said that the very old and infirm ones are expelled the society of the more vigorous.

3. SOUTH SEA.—The eared seals of the South Sea are more numerous and varied than those of the north; and some of them are of much larger size. One of the largest and most characteristic is

THE SEA LION of Forster and others (*O. jubata*). This species is said to grow to the length of five-and-twenty or thirty feet, and to measure sixteen or twenty in circumference where thickest. It is thus among the largest animals in the family. It appears to vary considerably in the different parts of the wide sea of which it has the range. The body is cylindrical, thick, and usually very fat; the head very small in proportion, and formed something like that of a large dog; the nose a little turned up and truncated at its extremity; the upper lip extends beyond the lower one, and is furnished with five rows of stiff hairs for mustachios; these are very long, and black in the young animals, but hoary or white in the old; the ears are conical, and not more than half an inch in length, and they are formed of very stiff cartilages; the eyes are large and prominent, and have the irides greenish; the fore paws are flat and black, with only the mere rudiments of claws; the hind ones have five very small claws upon each; the tail is conical and short; the fur upon the body is soft and generally of a yellowish colour; the female has no other covering than this upon any part of the body; but the male has a very conspicuous mane, or rather a covering of rough and coarse hairs along the whole upper part of the body; this is of a tan colour, not unlike the general hue of the mane of the lion; but all the rest of the body is covered with yellowish fur of a soft silky texture like that on the female. This species is said to eat sea birds when it can catch them, and even some seaweeds, as well as fishes, which are its principal food.

This is an exceedingly valuable animal, and the capture of it is pursued with much avidity. The flesh, though not the very best of animal food certainly, can be eaten, especially that of the young. The oil is abundant and excellent, and the fur is much in demand. It is also very widely distributed over the Pacific, being found in almost every latitude of that ocean, from near Behring's Strait to the extremity of America; but it appears to belong to the middle latitudes rather than the high ones in either hemisphere. The females make a sort of nest for

their young of the dry herbage on the beach. Notwithstanding the size and strength of this species, it is by no means a vicious animal; on the contrary, it is rather gentle and timid, except in the pursuit of its prey. In every point of view in which we can consider it, it is, in fact, one of the most interesting animals that inhabit the ocean.

FORSTER'S SEA BEAR (*O. Forsterii*) is a much smaller species than the one last mentioned; but it is one which is very widely distributed, and of which the fur is held in much estimation. It is found both in the high and the middle latitudes of the South Sea, in the most southerly isles that have been discovered, on all the rugged shores at the southern extremity of America, on the island of Tristan d'Acunha in the South Atlantic, on Van Diemen's Land, and the south of New Holland, on New Zealand, and all the islands which spot the south of the Pacific.

The length of this species varies from four to six feet. The body is slender, the head round, the opening of the mouth small, the eyes large, the ears conical and pointed, the fore paws free, with naked membranes, smooth on the upper side and furrowed on the under; the inner toe is the longest, and all the others are gradually shorter and shorter; the covering consists of two coats of hair, the one a very close, soft, and silky fur, of a reddish-brown colour, and the other of long, stout, and shining hairs, which are brown mottled with grey. The fine fur varies in colour in different individuals, and at different ages and seasons; it is thicker and longer on the neck and back than on the other parts; and it is the finer and shorter which is so much valued as fur. It is the proper South Sea seal-skin of the English furriers; and, as the long hairs are all carefully pulled out, it is remarkably even on the surface. It is also used in the manufacture of hats, often in producing what is called "short nap beaver;" but it is weaker than beavers' fur, and we believe does not either felt or retain the colour quite so well. It is said to be a wary animal, with a very acute sense of smelling, and therefore it is not easily captured. But it is so valuable for the fur, that every stratagem is put in requisition for obtaining it. As is the case in most of the other species, this one is subject to considerable variety, or else there are different species bearing a pretty close resemblance to each other.

LITTLE EARED SEAL (*O. Pusilla*). This species, which is the sea wolf of some authors, is not above four, or at the most five, feet in length, and two feet in circumference at the thickest part, even in the very largest specimens; while the majority of those met with are said not to exceed two or three feet. The head is round and a little depressed, and the muzzle very short; there are six incisors in the upper jaw, the two exterior of which have very much the form of canines; the mustachios are very long; and the ears, which are straight, are an inch and a half in length, which is more than those of any of the larger species; there are only four incisive teeth in the upper jaw; the neck is very thick for the size of the animal; the inner toe on the fore paws is very long; but the claws are very short and almost cornated in the skin; the hind feet are covered with fur on the upper part, but have the skin naked on the under; there are three well defined claws on the three middle toes of each of the hind feet; but the lateral ones are hardly perceptible; and the membrane by which the toes are united is divided into five very

long lobes, which extend far beyond even the most perfectly developed claws; the fur is soft and shining, and of a brown colour with a tinge of iron-grey; it is darker on the head and brighter on the back than on the other parts; on the ridge of the back it passes into bright grey, and into whitish on the belly. The young have the colour more inclining to blackish; and the adults are subject to considerable varieties of colour. This species is found in lower latitudes than many of the others, and occurs in considerable numbers about the southern extremity of Africa. But it has been differently described by different authors, and therefore there are some doubts as to its real characters.

PERNETTY'S LITTLE SEA LION (*O. molassina*) has the body slender, the head round, and the muzzle truncated so as to give it something the appearance of a bull-dog; the nose is rather prominent, and separated from the upper lip by a furrow; the upper lip closes over the under one, and the margins of both are covered with short stiff hairs placed closely together; the mustachios are disposed in four, five, or six rows over the greater part of the cheeks, and the hairs in them are four inches long in the parts most distant from the muzzle; these hairs are thick, flattened, and shining, and of a bright fawn colour; the eyes are placed at the distance of about two inches from the gape, and have the irides of a greenish colour; the ears are very thick, short, rolled together at the sides, nearly concealed with thick fur on the outsides, but naked within; the fore paws are short, and terminated by very large membranes, which are quite naked and of a deep black; there are only four rudimental claws on each of their feet; the hind feet are drawn close together, flattened, and have black claws about an inch long to the three middle toes, but mere rudiments to the lateral ones; the membrane on them is large and divided posteriorly into five produced lobes; the body and the upper surface of the extremities are covered with very close short fur; but the under sides are quite naked and of a bright and shining black, and the colour is reddish-brown, with a lustre like satin in the living animal; the tail is short, flat, and pointed; there are in all thirty-six teeth, the incisors divided into two lobes by a deep furrow. This species is found in the high latitudes of the South Sea, where it comes to the shores in abundance about the midsummer of the South Sea hemisphere, that is, in the end of December.

CROWNED EARED SEAL (*O. coronata*). This species is not known as a living animal, but only from a specimen in Bullock's Museum. That specimen was very small; and hence it is probable that it may have been the young of some other, and perhaps well-known, species. All the feet are described as being furnished with much larger and more powerful claws than the majority, or indeed almost any, of the eared seals with which we are acquainted in the living state. Our reason for concluding that it was merely a young one is the blackness of the skin, for many of those that are brown, when full-grown, are black in the younger state.

ASH-COLOURED EARED SEAL (*O. cinerea*). This one is not uncommon about the southern and south-western shores of New Holland. It grows to the length of eight or nine feet, and is covered with thick and hard fur of an ochre-grey colour, longer and thicker on the neck and shoulders than on the under

parts of the body. It is very doubtful, however, whether this is entitled to be regarded as a distinct species, for it rather seems to be a colouring of age; for individuals having all the characters of this one with the fur finer and of a yellow sand-colour, have been met with in the very same places. It cannot be too often repeated that there is really no trusting to colour as a means of specific difference among seals either with external ears or without; for any one who sees a herd of a dozen or two of common seals on a bank upon any of our own shores, will find some on the distant view nearly black, some piebald, some brown, grey, and some white. It would, therefore, be of some use to the systematic describers of these animals, to take a hint from Benedict's description of the lady of his choice, and let their hair be "of any colour that it pleases heaven," for the habitual introduction of colour into all the descriptions is productive of more confusion than any other cause that can be named. It is highly probable that the white-headed seal mentioned by Shaw is nothing else than the one which is here described as ash-coloured. It is described as being about ten feet long; the only distinction of it from the other is the white on the head, and the description is merely that of an individual specimen, the native habitat of which is not known.

THE YELLOW-EARED SEAL of authors, which is described as being of a pale cream-yellow, and less than two feet in length, is, in all probability, a young one at some particular stage of its growth; and the same may perhaps be said of most of the small ones which have been added to the list of species from mere museum specimens, and upon museum authorities, without the slightest reference to nature.

Such is as complete an outline of both the genera of the seal family, as well as of their characters and habits, as our limits will permit us to give. Taking them in the whole, there are very few families of animals, either of the land or the water, that are more interesting; and although their teeth and their alimentary system generally class them with the flesh-eating animals, they have some approximation to the *Ruminantia* in an economical point of view. It is to be borne in mind, too, that all the advantages which are obtained from the seal family, come from the free bounty of Nature, without care, culture, or feeding at the hand of man; and hence, if the period shall soon arrive (and there is no natural cause why it should not), when culture shall add the shores to the solid land, the value of the seal family may be greatly increased.

SECALE (Linnæus). Is the generic name of the well-known cereal rye. It is remarkable for being the habitat of a parasitic plant which fixes itself in the ovary of the flowers. The seeds and seed-vessels affected, instead of becoming normally developed, are perverted in an early stage of their growth, and a lengthened club-shaped body protrudes from the husks instead of the grain; hence it is called spurred or horned grain; and when used as medicine is called *ergot of rye*. The presence of this fungus alters the qualities and properties of the grain, changing it from a wholesome to a hurtful food, and even a fearful poison. Like many other poisons, however, the ergot forms, when duly administered, a valuable medicine, being peculiarly serviceable in one of the most interesting and hazardous conditions to which women are subject; indeed it may be fairly said, that the

discovery of the virtues of this little fungus has added a new article to our scanty list of specific remedies.

SECAMONE (Dr. R. Brown). A genus of tropical climbers, bearing pentandrous flowers, and belonging to the natural order *Asclepiadaceæ*. Some of the species are medicinal, and in our collections are treated as stove plants.

SECIUM (Brown, P.) A native of Jamaica, where it is called Choko. It belongs to *Cucurbitaceæ*, and bearing large fruit is cultivated for feeding hogs. It was called *Sicyos edulis* by Jacquin.

SECURIDACA (Linnæus). A genus of West Indian twining plants, bearing fragrant diadelphous flowers, and belonging to *Polygalææ*. They are stove plants, and succeed with the ordinary management.

SECURINGEA (Jussieu). A hard wooded timber tree called the Oiaheite myrtle, although introduced into our collections from the Mauritius. The flowers are monœcious, and belong to *Euphorbiaceæ*. It is grown on light soil, and flowers freely in our stoves.

SEDUM (Linnæus). An extensive genus of mostly succulent herbs, generally found in the northern hemisphere. The flowers are decandrous, and belong to *Crassulacææ*. From being frequently seen on the tops, or growing out of the interstices of stone-walls and rocks, they have acquired the name of stone-crop in English lists.

SELAGO (Linnæus). A genus of under-shrubs, natives of the south of Africa, bearing small didynamous flowers, and belonging to *Verbenacææ*. They are easy of culture and propagation.

SELENITE. The mineralogical name for crystallized native sulphate of lime. The primitive form of selenite is a rhomboidal prism, and the crystals are commonly transparent. Very fine specimens are found in Cumberland.

SELINUM (Linnæus). A genus of uncultivated herbs, natives of Europe. They belong to the fifth class of sexual botany, and to the natural order *Umbelliferaæ*.

SEMECARPUS (Linnæus). An East Indian fruit tree belonging to *Terebinthaceææ*. This is the marking-fruit of Indian authors, and so called because its stains are indelible, and it forms a natural ink. The fruit is not much esteemed unless roasted to remove its acidity.

SEMPERVIVUM (Linnæus). A genus of shrubs and under-shrubs, natives of the south of Europe. The flowers are dodecandrous, and belong to *Crassulacææ*. Being mostly succulent, they require a light loose soil, and but little water.

SENACIA (Commelene). A genus of tropical evergreen shrubs, natives of India. They bear pentandrous flowers, and belong to *Pittosporææ*. They are kept in the stove, and are easily propagated by cuttings.

SENECIO (Linnæus). An extensive genus of annual and perennial herbs and shrubs, chiefly natives of Europe and Africa. The genus is divided into six sections, each of which is separated into subsections. The flowers are composite, and among the species we find some highly ornamental, and many only worthless weeds. The *S. elegans*, and the *S. vulgaris*, common groundsel, are instances.

SENSITIVE PLANT. Is the *Mimosa sensitiva* of Linnæus; the irritable properties of which are so well known, even to those who know no other plant, that no description is necessary.

SEPIA (Linnaeus). A naked mollusc, universally well known by the familiar name of the cuttle-fish, and the dried calcareous internal support is used as a dentifrice. They are abundantly found in all climates, and many of them attain a considerable size. Under the article CEPHALOPHORA, this genus is more amply described.

SEPIDIUM (Fabricius). An extensive genus of coleopterous insects, belonging to the family *Pimplidae*, having the antennæ filiform, the fourth and following joints being obconical, the thorax depressed, with the lateral margins dilated, and with a dorsal channel. The species are destitute of wings, and are found in sandy and uncultivated districts, in the warmer parts of the old world; several species are found in the south of Europe. They are of a moderate size and black colour.

SEPIOLA (Leach). A species of naked mollusc of the genus *Loligo*.

SEPIOTENTHIS (Noblet). A species of naked mollusc of the genus *Loligo*.

SEPSIS (Fallen). A genus of small dipterous insects, belonging to the family *Muscidae*, having the body of a moderately elongated form; the legs long and slender; head globular, antennal joints small, with the terminal seta naked; palpi filiform. These are active little flies, generally of a shining black or bronzed colour, which are to be observed in summer upon various flowers and leaves in the sunshine, where they appear to delight in keeping their wings in a constant but moderately slow vibration. Some of the species exhibit various remarkable variations in the structure of the legs and some other parts in the opposite sexes. The type is the *Musca vibrans* of Linnaeus.

SEPTARIA (Lamarck; *SERPULA POLYTHALAMIA*, Linnaeus). A very long testaceous tube gradually attenuated to its upper end, and interiorly divided by vaulted separations, seldom complete, the extremity of which is terminated by two slender tubes without any interior partitions. This sheath, no doubt, incloses a bivalve shell at its end, but we have never seen a perfect specimen.

SEPTAS (Linnaeus). A remarkable genus, in so far as it is the only individual genus which constituted the fourth order of the seventh class of Linnaean botany. Every member of the flower has seven divisions. Jussieu has placed it among the *Sem-pervivaceae*.

SERAPIAS (Linnaeus). A genus of south European herbs, belonging to *Orchideae*. Like others of the order, the flowers are curious, and the species are so hardy, that they bear our winters with but a little covering.

SERICA (Mac Leay). A genus of coleopterous insects, belonging to the family *Melolonthidae*, having the antennæ nine-jointed; the body ovoid, as though inflated, and often silky or exhibiting various changeable reflections of colour; all the tarsal claws are bifid, and the thorax is much broader than long. These insects are of small or but moderate size; they reside in the perfect state amongst vegetables, of which they devour the leaves, the larvæ probably feeding upon the roots like those of the *Melolonthæ*. The type of the genus is the common English *Series brumæa*.

SEROLIS (Fabricius). A remarkable genus of crustaceous insects, belonging to the order *Isopoda*, and family *Cymothoideæ*, having the body depressed

and nearly circular, composed of transverse segments, four of which constitute the abdomen; the head is large, with the eyes placed upon tubercles, and situated upon the summit of the head. This genus is composed of two or three species of crustacea, inhabiting the southern extremity of South America, and in the form very nearly approaching to the extinct tribes of *Trilobites* (which see). The type of the genus is the *Cyathothoa paradoxa* of Fabricius.

SERPENTINE. Under this name are placed some of the most picturesque rocks which ornament and protect the British shores. Serpentine derives its name from the variety of tints which it exhibits, varying from a bright red to a vivid green. Some of the varieties admit of a fine polish when employed for ornamental purposes. Serpentine is seen in its highest beauty on the coast of Cornwall, where it forms the greater part of the Lizard promontory, and presents a series of natural arches and columns. At Portsoy in Banffshire it is associated with granite, and in other cases it is incumbent on beds of porphyry.

SERRATULA (Linnaeus). A genus of herbaceous annual, biennial, and perennial plants, mostly natives of Europe. They belong to *Compositæ*. Their English name is sawwort, and one of them, the *S. tinctoria*, is useful to dyers.

SERRURIA (Dr. R. Brown). A fine genus of evergreen shrubs from the Cape of Good Hope, and allied to *Protea*, and of course belongs to the same order; they also require similar treatment, and are well worth a place in every collection.

SESAMEÆ. A natural order containing four genera, viz., *Touretia*, *Martynia*, *Craniolaria*, and *Sesamum*. Of these genera there are eight species. The flowers are didynamous, and the plants are innocuous, and are used for both food and medicine. They are chiefly remarkable for the abundance of bland oil contained in their seed, which is as sweet as that of olives, and is expressed in the Levant and other eastern countries for domestic use.

SESBANA (Persoon). A genus of tropical plants mostly annuals, two of them are shrubs, one of which was called *Æschynomene* by Linnaeus. They belong to *Leguminosæ*. The species are potted in sandy heath mould, and require the hottest part of the stove.

SESELI (Linnaeus). A genus of annual, biennial, and perennial herbs, chiefly natives of Europe. They belong to *Umbelliferae*; none are in cultivation.

SESIA (Fabricius). A genus of lepidopterous insects, belonging to the family *Sphingidae*, having the wings horizontal, somewhat unclosed when at rest, and always more or less hyaline, and denuded of scales; the tongue is long and spirally rolled up when unemployed; the antennæ serrated in the males, and simple in the females, with a small bundle of scales. These curious insects have more the appearance of bees and wasps than lepidopterous insects; the abdomen is very thick and hairy, being terminated by a fan of scales. The caterpillars resemble those of the typical *Sphingidae*, having the body long and furnished with a dorsal curved horn near its extremity. They feed upon the leaves of various plants, and undergo their transformations under ground. The perfect insects fly with great agility, frequenting exposed situations in woods where various low spring flowers are in blossom. There are two British species; *Sphinx bombylifomis* (the narrow bordered bee hawkmoth) and *S. fuciformis* (the broad bordered bee

hawkmoth). They are of comparatively rare occurrence.

SESUVIUM (Linnæus). A succulent genus of plants bearing icosandrous flowers, and belonging to *Ficoideæ*. The species require to be placed in dry porous soil, and to be sparingly watered.

SETARIA (Beauvois). A genus belonging to the *Gramineæ*, found in hot as well as in cold countries. The *S. Germanica* is agricultural, and the *S. Italica* is economical.

SHADDOCK is the *Citrus decumana* of Linnæus, an East Indian tree of noble port, and bearing very large fruit, the largest indeed of all the citron family. Though far inferior to the orange for the table, or to the lime or lemon for medical purposes, it is a most useful fruit in those warm countries of which it is a native. Their appearance when on the tree is magnificent; a richer scene cannot be imagined than a grove of shaddocks, limes, mangos, guavas, &c., as may be seen in many places on the coast of Coromandel. The juice of the shaddock is fugitive, and therefore the fruit cannot be kept any great length of time, especially if laid on any hard substance. They are usually slung on light nets in cool air.

SHALLOT is the *Allium Ascalonicum* of Linnæus, a high-flavoured species of onion. Its offsets, by which it increases itself, are planted in the autumn or in early spring, and in the course of the summer a numerous addition of new offsets are produced.

SHARK (*Squalus*, or rather *Squalidæ*, the shark family). A numerous, powerful, and celebrated family of cartilaginous fishes, with fixed gills, forming, along with the rays (see **RAYA**), the second of the three families into which Cuvier divides the cartilaginous fishes, and the first of those that have the gills fixed, and openings in the sides for discharging the water when it is no longer fit for the purpose of breathing.

SELACHII is the name which Cuvier gives to the whole family, including the sharks and rays as sub-families; and as the sharks are the typical fishes, we shall here mention the particulars in which they and the rays differ from other fishes, and agree with each other, and with the true fishes that have the gills fixed.

They have the ordinary bones of the jaws wholly wanting, or at least only rudimental; and the bones of the palate, and post-mandibular bones, are the only ones furnished with teeth, and serve the purpose of jaws—very formidable, and indeed terrible ones in some of the species. One bone unites the rudimental jaw bones on each side to the cranium; and serves for the tympanic, the temporal, the jugal, and the preopercular bones in ordinary fishes. The *os hyoides*, or bone of the tongue, is attached to this single bone, and bears branchiostizial arches for the gills, which, however, are not so conspicuous to internal observation as those of the fishes that have the gills free. There are also gill-arches, but all the three pieces which usually form the skeleton of the gill-cover in fishes, are wholly wanting. They have all pectoral and ventral fins, the latter placed as far back as the vent, indicating that they are fishes of forward motion, rather than ascenders and descenders of the water. The habit is true to this part of their structure; for almost the whole of them swim near the surface, and all move rapidly through the water.

The gills are not free at the posterior edge as in other fishes, but fixed so that there is a separate current between every two, and then either all pass off

by separate openings, or are conveyed to a common canal. Besides the gill-arches, to which the inner edges of the gills are attached, there are cartilaginous arches embedded in the flesh opposite the exterior edges, and it is by means of these, probably, that the operation of breathing is carried on. This kind of breathing apparatus may, at first consideration, appear to be less perfect than that of the fishes with free gills; but in reality it is the very reverse; for, it is equally powerful and far more safe. Fishes which have the gills free can be drowned or suffocated, if the water enters their gills the wrong way; and thus they cannot remain in a current with their heads downwards. It is not, of course, any thing in the water that causes this; for the water is exactly the same, and the application of it must tend to produce the same effect on the blood of the fish, whether it enters the gills the one way or the other. But when the gills are free at the one extremity, a current of water entering the wrong way entangles the fibres, presses them against the arches, and of course stops the circulation of the blood in them. This cannot happen to those that have the gills fixed; and thus they can breathe the water with equal safety, let it enter which way it will. This gives to these fishes a power of endurance in the water which other fishes do not possess; and the power is not given them in vain, for they make vigorous use of it, not confining themselves to particular latitudes, but careering over the widest oceans, and braving the utmost turbulence of the waters,—better tempered to the perils of the deep than any other inhabitants of the sea.

There are other circumstances besides their security in breathing which assist them in this respect. Their cartilaginous bones make their bodies joint all over; so that they can yield every way to the muscles, and are perfectly secure from fracture. Their skins are also much firmer than those of the bony fishes, and thus give firmer insertion to the muscles. They are, in fact, a sort of intermediate between animals articulated on the internal skeleton, and on the external crust, and they thus partake of many of the advantages of both kinds of organisation. Their muscles are also differently constructed, as any one may see by comparing the flesh of a cod or a mackerel with that of a skate. In the two former, as well as in every bony fish that could be examined, whether with spinous fins or not, the flesh is always in flakes; whereas in the skate it is in long fibres. These fishes, by having their motion rather in the flexibility of the skeleton than in the articulation of it, and in having the muscles thus formed, are capable of moving upon any and every point of the body as a centre, while the motions are as powerful as they are varied.

But there are still other circumstances connected with the physiology of these fishes, which tend to give them additional powers of remaining in the sea, and being active and discursive in it, through the greater part of the year. Their mode of reproduction does not consist in the bringing forward of a vast roe and milt at one season, which demands a resort to peculiar grounds, where these may be deposited—an operation which exhausts all the other fishes very much. In some the young are hatched internally, and in all they are so fecundated. Those, too, which are excluded in the state of eggs, are each charged with the rudiment of a perfect and independent life;

and that life is far more secure than the life in the egg of a bird or an oviparous reptile, to which it bears, in some respects, a considerable resemblance. The shell or covering of the egg, in these fishes, is of a horny consistence, tough, strong, and not liable either to be broken or torn; and it is generally furnished with claspers or tendrils, which twine round the stems of sea-weed, and other fixed substances, where the eggs remain at a sort of anchor, until they are hatched. These eggs are, we believe, chiefly brought forward in pairs,—the ovoviviparous ones being hatched, one in each oviduct; and the oviparous ones receiving their horny covering there, in the same manner as the eggs receive their carbonaceous shell. The egg is usually of an oblong form, with the tendrils, one at each of the four corners; and those which are at the end to which the tail of the fish inside is to be directed, after it is formed, are stronger, and have more of a prehensile structure than those at the end where the head is to be situated. Near the head of the embryo fish there is a small longitudinal opening in the horny covering of the egg for admitting water; and at the opposite end there is a similar one for allowing the water to escape. Thus, the fish inside the close and firm case, has a supply of water as soon as it is capable of profiting by it. Near the head, too, there is a part where the horny shell is more easily disrupted than in any other; and when the proper time arrives, this gives way, and the fish comes forth a free tenant of the waters. But the transition from the one state to the other is not instantaneous, but gradual; for when the young fish comes out of the egg, it carries with it, in a capsule connected by a kind of umbilical peduncle, a portion of the same vitellus which had supported it within the covering. The general economy of the young shark (or ray) is, therefore, the same in principle as that of the spawning fishes; the case, or "purse," as it is called, when found empty on the beach, or floating, being the addition. Young salmon, for instance, remain "on the egg," and are supported by the vitellus, just in the same manner as young sharks are, only they are in vast numbers, in the sand or gravel, where they have been deposited by the parent fishes, and there is no protecting case to the young fish; whereas the young shark is not alone upon the waters, but provided with a case which affords it protection against the water, and also no doubt against enemies; for it is not likely that many fishes will feed on the eggs of sharks and rays, considering the strength of their covering; whereas many fishes, birds, and other animals, eat the eggs of the spawning fishes.

There is one other point connected with the economy of the young shark in its case, which is worthy of notice, as showing how perfectly the adaptations of nature are, even in what appear to us to be the most minute particulars. The young of the spawning fish is in the free water, and it has the free use of its mouth and its gill-covers, so that it can breathe in the same way that the full-grown fish breathes, from the commencement. It is different with the young shark, pent up as it is in its case, with the body bent, and the head confined. The water, too, gets access to it only by one small opening in the case, and it escapes by another. Hence, it is impossible that the young shark in the case can breathe in the same manner as a fully developed one does after it is in the sea. The case can clearly give it no assistance in breathing, as the case has no vitality. But the ani-

mal thus confined is placed in circumstances so different from those in which it is afterwards to act as the most independent and discursive inhabitant of the water, that it requires some assistance. The difference between the two states of the shark or the ray is not so great certainly as that between the state of a tadpole or a larva living in the water, and the batrachian reptile or the perfect insect living in the air; for the medium of breathing is different in them, and only the mode is different here. Therefore the desideratum is not a different kind of breathing apparatus for the two states, but a modification of the same apparatus. This is found to be provided in all the young of the sharks and rays that have been examined in the case. This consists of a filament of the substance of the gill, projecting from the gill opening, and containing a vessel (or vessels?) in which the blood is exposed to the action of the water; and thus the same purpose is answered without the action of the internal gills. When the shark or the ray comes into the free water, those fibrous appendages would be as inconvenient as they are necessary when it is in the case; and they are accordingly very speedily absorbed.

One can hardly fail in being struck with the resemblance which there is in these supernumerary gills in the selacian fish, while in the case, to the gills which those reptiles and insects which spend the first stage of their animated existence in the water have while they remain there. In them the gills are no part of what is to be the permanent structure of the animal, they are mere external appendages developed for a temporary purpose; while they answer that purpose, the proper organs which are to be prominent are either undeveloped or dormant; but they are formed or become active as soon as they are wanted. Just so in these fishes, the internal gills remain in a great measure inert, until the animal comes into the free water, and requires their use.

This provision in the young shark or ray appears, after it has been explained, to be so very much in accordance with the general action of nature, that one looks upon it as a thing indispensable, and therefore of course. But this is only *after* the explanation has been given; for before then, some naturalists of no mean name or industry considered these appendages as characteristic of a species of shark, which had been met with only in the small specimen which had them, and to which they gave the name of *Squalus ciliaris*.

This shows how necessary it is for every one who puts his hand to the subject of natural history, more especially in the *finding* of new species or varieties to which tyros in the matter are exceedingly prone, to inform himself well upon all points of physiology, both immediate and collateral; for it is highly probable that very many of the obscure species in general, which rest upon no surer foundation than a single museum specimen, would be found entitled to no such distinction, if their physiology and place and relation in nature were rightly understood.

The *Selacii*, but especially the sharks as the typical subfamily, being thus formed by nature for the most powerful exertions, and being exempted from some of the severest duties that devolve upon other fishes, may fairly, on the principle of the general analogy, and even without a distinct knowledge of their habits, be presumed to have a very energetic and important part to play in nature.

Now though the sharks cannot be said to be the monarchs of nature's productions in the ocean, as the *Carnivora* are on the land, or the birds of prey in the air, yet they are unquestionably, in some of the species at least, the most powerful, the most active, and the most sanguinary of the fishes. The only inhabitants of the water which have so much the mastery of them as to be able to make a meal of a large shark of the most formidable species, are the great-toothed whales; and they are mammalia, not fishes. We must therefore assign to the sharks the rank of the "monarchs" of the fishes, or rather perhaps the "tyrants," for, as these names have been applied in the animal kingdom, they are perfectly synonymous; and the only attribute of kingship to which they have any claim is power—the power of gratifying their own appetites by eating up the rest. As monarchs stand among men at the present day, they would of course account this as a very undesirable and repulsive kind of royal endowment or dignity; and they would be right in so doing, while those who thus attempted to narrow them and rob them of the very jewels of their diadems, even in words, would be very wrong and very wicked; but still the kings of beasts and of birds, which have won their honours from times very remote, tell an unfavourable tale of the kings of those very early times; for likeness in disposition and conduct is the only ground that we can see or imagine for applying the name to the animal. Be that as it may, these monarchs of the fish take more after the birds of prey than they do after the carnivorous mammalia; for the females among them are always larger and more powerful than the males.

The deadly weapons of the shark family are not confined to the teeth, formidable as these are, for some of them have the snout drawn out into a toothed weapon, more formidable than that of the sword-fishes of the mackerel family. Indeed, it seems to be the shark which is so armed, and which is sometimes called the "sea-sword," and not the sword-fish, which is described as making its gashes upon the whale. This is reconcilable both with the nature of the fish and the seas in which it is found. The tail of some of the sharks is also a most formidable weapon; and the fins and even the skin of the animals are of a cutting or wounding nature, from the hard tubercles with which they are beset. They differ so much in the details, however, that no general description can be so framed as to meet them all; and they are so many that a full detail of them would greatly exceed our limits.

We may mention, however, that the teeth of these most active and voracious fishes are of two distinct kinds, both wounding teeth, if of sufficient size for the work; but the one kind better formed for tearing and laceration than the teeth of any other animals, whether of the sea or the land; and the other kind more adapted for keeping their hold. The first kind consist of single blades, of a sort of triangular shape, standing upon one of the three sides as a base, and having the side which is directed toward the central line concave, and the other one longer and convex. These two edges are thinned off for cutting, and at their junction they form a sharp point. They are also toothed like a saw along both their edges, the points of these secondary divisions being all turned in the direction of the principal point of the entire teeth, and all trenchant in their edges; so that the utmost ingenuity of savage man, when he forms his

weapons so as to tear and torture as well as kill, could invent nothing more adapted for his revolting purpose than this kind of tooth in the shark. And, wherever the animal is furnished with this terrible weapon, it is never given in vain; for the murderous disposition of the owner always corresponds.

The other kind of teeth consist of one principal blade, formed something like the point of a broad arrow, but curving outwards towards each side at the base, and having a small trenchant tubercle on each. The teeth of this latter form are curved backwards toward the opening of the gullet.

Neither kind are rooted in the bones, and the cutting teeth especially are supplied with muscles, so that each tooth has various motions independently of the others, or the whole may move in concert according to circumstances. One can indeed imagine nothing more terrible than those teeth, when they are mustered row upon row, to the number of six rows, all at work upon the victim, and plied by the strength of a most active animal, from thirty to thirty-five feet in length, and weighing nearly three quarters of a ton.

Yet terrible as these teeth are, and well as they are fitted for inflicting the most fearful lacerations, they and the animal that is furnished with them are true to the general character of the class—they are still the teeth of a fish; and their grand action is prehension and swallowing, not killing and dividing their prey. As is the case in fishes generally (though not quite universally), the stomach of the shark is fitted for performing the whole work of assimilation without any preparation of the food by the mouth. If it can be obtained without a struggle, the largest prey that the shark can swallow, and its gape is no stinted one, goes to the stomach entire. Large fishes, seals, the bodies of various animals of considerable size, human bodies—an entire one and part of another, nay, even the body of a horse (so say the reports), have all been found entire in the maw of the most formidable of the shark family.

The whole are not indeed of this very terrible character; but the greater part are, and the peaceable ones are comparatively few, though many have the teeth small, and the majority have them not of the lacerating character. We must therefore take one brief survey of them in the order of the arrangement. In this we shall follow Cuvier, who makes four sections or principal genera—sharks, hammer-heads, angel-fishes, and saw-fishes. The ray follows as a fifth, and completes the family of the *Selaci*, but we have already noticed it in the article above referred to.

The last then of the four now mentioned contain only a single genus each; but the sharks, or family of the *Squalidæ*, consist of twelve subgenera, *Scyllium*, *Carcharias*, *Lamna*, *Gallus*, *Mastelus*, *Notidanus*, *Selachus*, *Centracionus*, *Spinax*, *Centrina*, and *Scymnus*. Many of them, however, are very little known; and they are so many that we can only notice such as are found in the British seas, or are otherwise of very great interest.

SCYLLIUM. The members of this genus are generally called "dog" fishes on the British coasts; and indeed there is a great disposition to name the whole of the family that occur with us to common observers after some one or other of the varieties or species of the canine race. The characters of the genus *Scyllium* are: the head short, the muzzle blunt, the snout

trils near the mouth, and continued by a groove to the upper lip, thereby forming a sort of valves; the teeth of the prehensile description only, without any of the serrated or lacerating ones, but with sharp points and a tubercle at each side of the base; the gill-openings five on each side, the last ones opening over the pectoral fin; the first dorsal rising on the mesial line about half-way between the snout and the extremity of the tail, and in rear of the ventral fins, the second dorsal in rear of the anal, the caudal narrow at the tips, and the principal lobe on the under side of the tail. The males with claspers to the ventral fins, as is general in the family, but the females without these appendages.

The fishes of this genus, and indeed those of the greater number in the family, are social at certain times of the year, and pursue their prey in packs. They are found chiefly near the rocky shores where there is sea-weed. They are more common on the warmer shores than on those of Britain, and on the south coasts of England than on those of Scotland. They are oviparous, and deposit their eggs in small numbers at intervals among the aquatic plants. Their flesh is little esteemed, and thus they have small interest in the eyes of any persons but naturalists.

In treating of the shark family, and indeed of most of the cartilaginous fishes, it is necessary to use some caution, and not speak too particularly about the size. There are differences, no doubt, in the average sizes of the different species, and very great differences; but there does not appear to be any thing positively to limit either the size or the duration of any of the family, as their bones do not become indurated; and thus there seems no reason why their enlargement should cease altogether. This precaution is, however, necessary in a general point of view only; for of course we may allude to the size either of the largest or the average as met with in any particular locality. There are three species of the genus found on the British shores, one very plentifully in some places, another much more rarely, and the third is very rare, or, which amounts to the same, it is rarely seen. They are all called dog-fish; but none of them is the dog-fish so plentifully found in the northern parts of the British seas. Wherever they come, they get very little thanks for their appearance; for they are of no value themselves, and they are so voracious that they drive the more valuable fishes off the grounds, and so strong that they are apt to break the nets. Where there is fishing with lines, they are apt to plunder the hooks.

Small spotted Dog-fish (S. canicula). This is the one which is most common on the British shores, especially those of the channel; but, as Mr. Yarrell justly observes, it is not very easy to decide whether the comparative "small" should be applied to the fish or the spots. Cuvier calls it the "large" one, and the other the small; in this he follows the other continental naturalists, and the comparative size can be much better judged of in the Mediterranean than in our seas. The snout of this one is much shorter than that of the other; but the body and tail are longer in proportion to the thickness. The ground colour of the upper part is reddish, mottled with reddish-brown spots of a shade considerably darker, and the spots on the fins larger than those on the body; and the ground colour passes gradually into white on the lower parts of the sides and the belly, the middle of which is without any spot; but there are spots on

the lower fins, though not so numerous as on the upper ones. There is a sort of "grain" or granulation on the skin, but the tubercles which form it are very minute and inclined backwards, so that the roughness cannot be felt if the finger is moved in the same direction as the points slope.

Large-spotted Dog-fish (S. catulus). This appears to be about the same size as the former; but the spots are much larger and more conspicuous, and they are of two colours, the larger ones nearly black, and the smaller ones paler than the ground, which in the upper part is not so red as in the other species. The snout is larger and more pointed. This species is much more rare than the former.

Black mouthed Dog-fish (S. melanostomum). This is common enough in the warmer seas, but exceedingly rare on the British shores. It is a more handsome fish in the colour of the body than either of the other two; and the head is more tapering and the snout more elongated. The upper part is brown with darker spots, surrounded by margins of lighter, and also variously clouded. The inside of the gape is black, hence the name. Mr. Yarrell is the first who has noticed it as a British fish, on the correct information of Mr. Couch.

There are several more species of this genus mentioned; but they, or indeed the ones that we have noted, are not of much interest to a general reader.

CARCHARIAS (Sharks properly so called). The generic characters of these are: the jaws and head depressed; the nostrils near the point of the snout; the teeth pointed and trenchant, often toothed in the edges in the manner described; first dorsal and pectoral fins large, the dorsal behind the pectorals, but before the ventrals; the second dorsal much smaller; the caudal varying so much in the different species as not to form any part of the generic character.

This is the genus, some of the species of which are so much dreaded, and dreaded with so much reason, in the warmer seas, though the more formidable of them rarely, if ever, visit so high latitudes as those of Britain. The species are so very numerous, that the details of them would extend to a very great length. All that we can do, therefore, is to notice one or two of those which have the best authenticated history.

We must premise, however, that though the arch-destroyer of all the sharks has been mentioned by the writers on British fishes as having occurred sometimes on the one part of the coast, and sometimes on the other, yet the fact of its having actually done so is not yet clearly established. The tremendous powers of "the white" shark, and the fearful effects of them in those seas in which it abounds, have become, as it were, the story of all sharks; and when the appearance of a shark is rumoured on any part of the coast, the rumour is very apt to become the whole history of the white shark, before it travels half its round; and some one is generally found ready enough to record the romance along with the reality. That the white shark may have been in the British seas, we do not mean positively to deny, for the powers of the animal are quite adequate to carry it into any sea, or fairly round the earth: all that we contend for is, that up to the present time there is no direct and conclusive evidence of its so appearing. We must, therefore, give our short notice of this formidable species as an inhabitant of other seas, in which it is seen but too frequently.

White Shark (C. vulgaris). The body is long, covered with a hard tuberculated skin, of a brownish-ash colour on the upper part, and whitish below. The head is large, the muzzle not very long, and depressed, and pierced with numerous pores. The tongue is short and rough. The upper jaw furnished with six rows of triangular teeth, with both their trenchant edges nearly straight and toothed; and the under jaw with four rows, sharper in the points than the others, but not so thin, and therefore not so trenchant. The pectoral fins very large, and the first dorsal elevated, with the ends of all the three broader than their bases, and squared over, or slightly concave. The ventrals small; and the second dorsal and anal, which are opposite to each other, not very large; but all the four of similar shape and termination as the larger body fins. The caudal fin forked, with two powerful and widely divergent lobes, the upper one larger than the under. The irides with a pearly lustre. This is the description of the fish as it appears in the Mediterranean, and therefore that in which it is most likely to appear, if it should stray to the shores of the British seas. As a probability, if not a proof, that the descriptions of it as a reputed British fish, have been mixed up with that of some other species, probably the Porbeagle (*Lamna Cornubica*), we may mention that there are inserted the words, "pectorals triangular," "first dorsal rounded," which are true of the porbeagle, but not of the white shark.

White Shark.

In the tropical seas the white shark attains the length of thirty or thirty-five feet; and the mouth of one of this size is a fearful chasm. It is deeply cleft, and the opening is made almost to a circular aperture between three and four feet in diameter. This will account for the large animals that have been found entire in the maw of this monster of the deep. The French call this species *Requin*, which is usually said to allude to the vast number of victims which the jaws of the shark send to their final "rest," or prepare for their "requiem," or song of last repose. Whatever of truth there may be in this, the shark is terrible upon the sea; and scenes of death and destruction are said to be those in which it is most in its element. We question the accuracy of those statements which impute to the shark the power of "scenting the battle from afar," or even what is said of its smelling putrid substances when miles off; but it is very generally stated by nautical men who have been engaged in the warm seas, that the shark en-

joys the scene of carnage; and that unscared by all the terror of the battle, it adds a new terror of its own, more revolting, if possible, than any of those perpetrated by man. The sharks career about from vessel to vessel, swallowing or mangling the bodies of the fallen, the dying and the dead—all, in short, who by accident get into the water; and adding its share to the spilt blood with which the surface of the sea is clouded.

When the slave trade was carried on with all the horrors of "the middle passage," at which, even in the recollection, our blood runs cold at the present time, it afforded a formidable stock on which to graft all the horrors of the accompaniment of the shark. There was, of course, enough, and more than enough of the horrible in the abominations of the trade itself, without this addition; and as the sharks are careering about the tropical seas in all directions, there was every probability that the poor unfortunates who had expired in the "gross intolerable air of the floating engines of wholesale murder," were swallowed by the sharks the moment they were cast into the sea, yet it by no means follows from this that the sharks had any means of distinguishing between a slave ship and any other ship whose keel might divide the waters of their seas; but there is little doubt that the sharks, in common with all the other races of discursive fishes which roam the broad waters, would follow that from which they had been once fed, in the expectation of being fed again; and thus a very little addition of romance would suffice to bear out all that was alleged of them.

It would be foreign to our purpose, however, to enter into the details of the history of the white shark, whether romantic or real. They are to be found in the narrations of the voyagers; and all that we need to add is, that the powers of this shark, and the propensity which it has to put those powers into operation, are quite equal to all that has been alleged of it; and thus, all who have a thirst for believing which is not absolutely insatiable, may find ample scope for it within the limits of the real history of these animals. There is but too much reason to believe that legs have been lopped off, bodies cut in twain, and members swallowed entire by these fishes; and some of the most melancholy instances have been those in which the commander of a vessel, in probably an overstretch of that kind of authority which such have on the high seas—and we readily admit that they need a good deal, and no little promptitude and decision in the exercise of it—have made immersion in the sea at the end of a rope the punishment, and have drawn up half a human body instead of the whole.

The teeth of the shark are well calculated for performing all the feats that have been recorded of it. We have already mentioned their arrangement, and we shall now notice their size. In the largest sharks that have been examined, that is, in those about thirty-five feet long, the teeth stand fully two inches clear of the jaw, and the base is nearly of the same extent. They are serrated in the edges, slightly concave toward the mesial line, exceedingly hard and white, and having their principal individual motion toward the mesial plane, though they cut and tear in their motion both ways. In the young fishes there is only one row, and the teeth composing it are partially inclined toward the throat; but they increase with age till the adult number of six above and four below has

been produced. Whether this is the ultimate number which they never exceed, or whether the new rows are produced external or internal of the former ones, are points which have not been ascertained, though it is generally supposed that the inner rows are always the last produced. Some have gone so far as to say that the supplemental rows are produced for the purpose of supplying any deficiency that there may be in the external or primary row; but this is not at all probable, as the whole of the rows are in general equally perfect. Whatever may be the number of the rows, the teeth in the inner one have always more of the swallowing character and less of the tearing than those of the external rows; and there is every reason to believe that the teeth continue increasing in size as the animal itself increases.

From this armature, and also from its great muscular power and the texture of its skin, the shark has few enemies of whom it can be in much dread. The skin of the shark is so hard and rough in the texture, that no animal would be fond of biting it, while it bites and also strikes very powerfully. The great spermaceti whales are the only animals which can master it; and it makes a powerful resistance even to these. This resistance is not, however, ultimately successful; for a shark seventeen feet in length has been found in the stomach of one of these whales. There are other enemies of much smaller size, which are perhaps more annoying to the sharks than these powerful whales, namely, various descriptions of *entozoa*, which infest their alimentary canal. It is probably the annoyance given by these internal tormentors which sometimes forces the sharks on shore in great numbers, though single ones often run themselves aground in the eagerness with which they pursue their prey. Their eagerness for food is so extreme, that they will leap out of the water, Commerson says, to the height of twenty feet in order to seize a tempting bait. The large ones follow the pretty general law of fishes in eating the smaller ones of their own species. Hardly any substance, indeed, comes wrong to them, so that it is animal matter and in mass enough. Seals, fishes, and mollusca are indiscriminately eaten, the last of which of course are only the larger ones without shells, which are so very abundant in the various seas. They, in fact, perform the same office in the water as the more powerful of the carnivorous animals perform on the land—namely, that of arch-scavengers; only as the element in which they display their powers is much more extensive, their powers of motion are far greater both in energy and continuance. As is the case with the predatory mammalia too, the most formidable of them, of which there are several species, or, at all events, varieties, known by the common name of white sharks, are confined to the warmer latitudes. Some of these have the pectoral and dorsal fins pointed, the posterior rays very short, and the terminations concave, and have the colour more inclining to grey than it is in the typical white shark. It is also more or less spotted; and the tail and caudal fin, and indeed the whole appearance is intermediate between the typical white shark and the genus *Scyllium*.

Sharks, though most of them inhabit near the surface of the water, are remarkably tenacious of life; resembling in this respect, and also in the length of time that their flesh will keep, the bottom fishes with bones more than the surface ones. This is, in part

at least, owing to the different structure of their gills, which prevents the shrivelling and stoppage of the circulation, which are the causes of death. This tenacity of life has caused the sharks to get a sort of romantic credit for qualities which they certainly do not possess. The larger ones are, as we have hinted, apt to swallow the small ones of the same species; and on opening a large shark small ones have been found alive in the stomach. From this it has been inferred that the mother takes the young into the stomach as a place of safety. But the stomach of a shark is about the least safe place into which any animal can get, and whatever substance is conveyed there may always be considered as conveyed for the purpose of being eaten. It is not so much of the white shark that this maternal tenderness is alleged, but of the blue one, which comes into higher latitudes, and is better known.

THE BLUE SHARK (*C. glaucus*) is also a formidable animal, though much less so than the white shark. It is very common in the Mediterranean; but it appears seasonally on the south coasts of Britain, and occasionally ranges as far as the extreme north. When it appears on our shores it is seldom more than six or seven feet in length, at which age it has three rows of teeth in each jaw. From this circumstance, one would conclude that it is not then nearly full grown; for the teeth are supposed to increase in number, much in the same way as in the white shark; as the number of teeth is the same in both jaws at this, which may be considered as the middle age of growth, it seems to follow that both jaws get additional teeth at the same rate until the under one has got its complement, and then the farther additional ones come in the upper jaw. These extra rows, as it were, which the upper jaw contains, appear to act along with the rough surface of the tongue in the operation of swallowing.

The teeth of the blue shark differ a little in their form from those of the white one. The sides toward the mesial line are more hooked than those of the other, while, in the cases where there are only three rows, three or four at the middle of the row have more the character of swallowing teeth. The body is longer in proportion to its thickness than that of the white shark; the snout is also proportionally longer; and the fins are differently shaped. The first dorsal is not very high; it is rounded in the fore part; and very low in the hinder. The second dorsal is small and low. The pectorals are long and falcion-shaped, with their curvature directed backwards. Their anterior margin originates under the fourth breathing hole, which holes, as in the other members of the genus, are five in number. The ventral fins are placed about midway between the positions of the two dorsals, and the anal midway between the last dorsal and the caudal. The caudal has the upper lobe much longer than the under one; and the membrane of a portion of it toward the point is enlarged into a sort of truncated flap. The under part is nearly as white as in the former species; but the upper parts, the head, the irides, the upper fins, and the upper surfaces of the pectorals, are clear slate-blue. In the young specimens the teeth are very small; but they become more formidable in the full-grown ones.

We quote the following notice of it by Mr. Couch, from Mr. Yarrell's second volume. "The blue shark is migratory, and I have never known it to arrive on the coast of Cornwall before the middle of June; but

afterwards it becomes abundant, so that 'I have known eleven taken in one boat and nine in another in one day. The injury they inflict on the fishermen is great, as they hover about the boats, watch the lines (which they sometimes cut asunder without any obvious motive);—fishes never have any motives, obvious or lateral,—“and pursue the fish that are drawn up. This indeed often leads to their own destruction; but when their teeth do not deliver them from their difficulty, they have a singular mode of proceeding, which is by rolling the body round so as to twine the line about them for its whole length; and sometimes this is done in such a complicated manner that I have known a fisherman give up any attempt to unroll it as a hopeless task. To the pilchard drift-nets the shark is a still more dangerous enemy, as it is common for it to pass in succession along the whole length of the net, cutting out, as with shears, the fish and the net that holds them, and swallowing both together.”

On the fishing-grounds in the northern parts of the British seas, these sharks are not so destructive, because a stray comes only now and then. When one makes its appearance on the coast, however, it causes much more alarm than the same recurrence does on the coasts of the Channel; and the report of there being one puts an end to bathing in the sea, at least for a considerable time. It is not probable that any appear of such size as to be capable of swallowing a human body; but there is no doubt that they could and would inflict terrible bites. The rumour is, however, always less or more mixed up with the notion of the white shark, and this gives it a terror which does not naturally belong to it.

The time and manner of the coming of this fish into the British seas is a tolerably good means of judging of the movements of those fishes which it follows, as well as of its own movements. It always follows the surface fishes when they shoal toward the land; and so it must follow them from the warmer latitudes rather than from the deep water.

The Fox Shark (C. vulpes). This fish is also called the “Thresher,” from the use which it makes of its tail as a weapon both of offence and of defence. It occurs occasionally on the British coasts, but it is far from being common. It is a very roaming animal, and is found in higher latitudes than any of the two former species. Its gape is not so wide, or its teeth so formidable in proportion to its size, as those of the former sharks; but its tail is a most powerful weapon, and it is exceedingly bold and voracious. The snout is short and pointed; the body very stout; and the upper lobe of the tail-fin about the same length as the whole body and head. The pectoral and first dorsal are long and strong, and much falcated; the ventrals are small; and the second dorsal and anal little other than mere finlets. Both lobes of the tail are falcate, the lower one having nearly the same form as the pectoral fins, but shorter and very much pointed. The length of the largest specimens which have been found in the British seas has not exceeded twelve or thirteen feet; and that which is circumstantially described by Mr. Couch was “ten feet ten inches on the straight line, and ten inches more on the curve; three feet four inches round where thickest; solid at the chest; conical from the snout to the pectoral fins, and thick even to the tail, which organ from the root was five feet and a half long, and consequently more than half the length of the body (the head and tail

included, of course); the eye prominent, round, hard, four inches from the snout; iris blue, pupil green; the nostrils small, and not lobed; mouth five inches wide, shaped like a horse-shoe; teeth flat, triangular, in two or three rows, not numerous; spiracles five; pectoral fins wide at the bases, pointed, eighteen inches and a half long. Measured along the curve, from the snout to the first dorsal fin, two feet five inches, the fin triangular; from the first dorsal to the second, fourteen inches and a half; this and the anal fin small, triangular; skin smooth; lateral line central and straight; breadth of the tail, including both lobes, thirteen inches; the upper lobe narrow throughout the greater part of its length; and on the lower margin, at four inches from the extremity, is a triangular process. Colour of the body and fins dark blue, mottled with white on the belly.”

Fox Shark.

This circumstantial description, together with the figure, will enable the reader to form a tolerably correct idea of the appearance of this curious fish; and when he does so, he will not fail to see how well it is adapted for the part which it plays in nature. The body is obviously formed for speed and for the working of the tail jointly. The form and power of the pectoral fins and the first dorsal give it a firm hold on the water at that part; while the smallness of the fins on the posterior part of the body allow that to give free scope in all directions to the tail. Nor must we overlook the power of muscle, which is continued to the very base of the caudal fin. From the length, strength, and parallelness of the forward fins, the body can swing on them as on an axis; and as there are three of them, the plane of that axis admits of much variation. When the body of the fish has a hold of the water by means of the long fins, and the tail moves in the air, the force with which it can strike an object at the surface must be very great. “Mr. Couch,” Mr. Yarrell remarks, “says it is not uncommon for a thresher to approach a herd of dolphins (*Delphini*) that may be sporting in unsuspecting security, and by one splash of its tail upon the water put them all to flight, like so many hares before a hound.” Other authorities say that the thresher is in constant hostility with all the smaller *Cetacea*; but the “motive,” as it is called, is not quite so apparent. That this fish should swallow dolphins is out of the question, for an ordinary dolphin is more than six times the volume of an ordinary thresher. From the one which Mr. Couch describes, as well as from the size and character of the mouth, it appears that the food consists of fishes of small size. The one in question was taken in a salmon-net; but young herrings were found in the stomach; and Mr. C. adds, that it appeared not to be able to cut its way out of the net, as the blue shark would very readily have done, and nothing is said of any kind of attack made by it upon the salmon.

Still, the fact of its not only astonishing the dolphins, but inflicting pretty severe chastisement on the whalebone whales, has been so often stated, that there appears to be no doubt that it is true, though, how it could feed on these very large animals, is another matter. But it may bear them a grudge upon other grounds as rivals in its feeding, for the small cetacea are great devourers of fish. We quote from "Griffith's Cuvier" the following passage, which probably relates to this shark, and which, from the authority on which it rests, cannot be doubted:—"When Colonel Smith was in Jamaica, the captain of a West Indian vessel happened to be upset in his boat, along with two boys, about two miles distant from the land of Montego Bay. This occurred in the night; and the three, with the aid of an empty keg and billets of wood, betook themselves to swimming. The boys soon disappeared one after the other; and the master, from the length of time during which he had been in the water, became quite exhausted and droway. From this state he was suddenly, and not very agreeably, roused by a tremendous blow on the breast, proceeding from a shark which darted against him from below. The man defended himself with his billet of wood, and fought the monster for a long time, until he was at last heard from the shore by some negro watchmen, who went with a canoe to his assistance, and brought him to land. The Colonel believes that he had then about forty wounds, but had lost no limb. The escape was attempted to be explained by the probable conjecture that the shark had already devoured the two boys, and had therefore become too unwieldy to bite with sufficient effect. The wounds were indeed mostly cuts inflicted with the fins of the fish. The Colonel visited the estate where the captain had been cured, a few days after his departure, and learned the circumstance from the medical resident who had attended him."

This could not have been the white shark, for its habit is to bite, or to swallow entire, so that it has no need to strike with the fins; and there was no evidence of a direct bite of any kind inflicted on the captain, or that the boys had been devoured by the fish. In fact, the characters of two different species have obviously been mixed up in this case, as they have been in very many others; and we are still in the dark as to the real purpose of the flagellation which the fox shark is said to inflict upon its more bulky neighbours. The analogy would lead us to suppose that the tail, powerful as it is, is a weapon, and not a feeding instrument. This is the chief use of all the weapons with which the bodies of fishes are furnished, with the exception of the furnishing of the mouth; and though this shark should advance, and apply this weapon, that does not in the least alter the character of it.

There are many other species or varieties of the genus *Carcharias*, but very little is known of their habits as different from the three that have been mentioned, and therefore they must suffice in the meantime.

LAMNA. The best known species of this genus is the *Porbeagle*, of which we shall speak more particularly by and by. The generic characters are: the snout conical; the nostrils in the under side; all the gill-openings in advance of the pectorals; the first dorsal only a little in the rear of the pectorals; the rest of the body-fins small; the second dorsal

and anal near the caudal; both lobes of the caudal large, the upper one not much longer than the lower, and margined on the posterior edge near the lip; and the teeth much more of a prehensile and swallowing character than of a tearing one; they have large triangular points, with a small lateral tubercle at each side of the base. They are known only, or chiefly, in the European seas, and not in the tropical ones, like the true sharks. They are not so formidable as these, but still they are ravenous fishes, swimming with much velocity, and growing to a large size.

The Porbeagle (L. Cornubica). The common name of this fish appears to be compounded of *Poresse* and *Beagle*—the former from its bearing a slight resemblance in shape to that well-known member of the cetacea, and the latter from the fact of these fishes being often found hunting their prey in packs. It is called *Cornubica*, from having first been correctly described from specimens taken on the coast of Cornwall. As a British fish, it is not, however, confined to the Cornish coast, but is fully as common on the northern shores as the southern. They are very discursive fishes, and, as they do not come into shallow water, they are seldom seen in proportion to their numbers.

The body is spindle-shaped, thick and round at the middle part, pointed in the snout, and tapering very much to the tail, where there is a lateral keel on each side advancing to some distance forward on the body; the head is furnished with numerous pores, which give out a gelatinous secretion for lubricating the skin; backwards the skin feels quite smooth, but forwards it is rough to the touch; colour blackish grey above, on the under part white; the pectoral fins moderately large, slightly falcate, and of a black colour; the first dorsal high, broadly lancet-shaped, with a low prolongation backwards; the second dorsal nearly the same shape, but very small, and near the caudal; the ventrals very short, inclined backwards, and terminated in a straight line parallel to that of the body; the anal fin, under the second dorsal, very small and rounded; the caudal partially crescent-shaped; both lobes long, but the upper the longest; lateral line straight, and on the middle of the side; the gill-openings five in number, the last beginning at the anterior base of the pectoral fin, and bearing obliquely backwards; the eyes round, and deep blue; there are three rows of teeth in the mature state, but the fish grows rapidly, and thus is often found of considerable size with only two. The porbeagle is found chiefly in the currents near rocky places, and feeds on fishes of considerable size, swallowing entire those which measure as much as two feet in length.

Beaumaris Shark (L. Monensis). This is known only as a British, or rather as a Welch fish, and only two specimens have been met with, both of which are described by Pennant. They were both found at the same place, the Anglesey side of the Menai Strait. The snout is blunter than that of the porbeagle, and the pectoral and first dorsal still farther backwards, and more falcate; the ventrals larger than in the others, and the second dorsal and anal rhomboidal; the tail more completely crescent-shaped; the lobes more tapering, the upper one larger in proportion, and more of the posterior edge margined toward the tip; the skin is nearly smooth, and lead-coloured. The habits of this species are of course altogether unknown.

GALEUS. This genus, of which only one species is known, more nearly resembles the true shark than the one last mentioned does. The chief differences are, that this genus has air-holes, and the teeth are serrated in their outer edges only. It is a long and slender fish, attaining the length of five or six feet. It is not very common on any part of the British shores, and it occurs chiefly on the south. The young are produced, all at one time, to the number of thirty or more, in May or June, and they remain during the winter; but the full-grown ones leave the coast at that time. They are very voracious, but not nearly so injurious to the fishermen as the blue sharks.

The skin is smooth, the lateral line straight, the muzzle long and flattened, the nostrils near the mouth, and with valves; the jaws are semicircular, with small teeth nearly the same in both; the gill-openings small, and close together; the pectorals and first dorsal triangular; the other body fins rhomboidal; the upper lobe of the tail short, and at the extremity, the under one much larger, and divided into segments; colour bluish grey on the upper part, and greyish-white on the under. The flesh is not eaten; but, as is the case with all the shark family, a considerable quantity of oil is obtained from the liver. The *Common Tope* is the English name of this fish, and the systematic one is *G. vulgaris*. It is not a fish that is sought after by the fishermen, who give it very little thanks for its appearance.

MUSTELUS. With the exception of the teeth, which are pointed and flat like those of the rays, this genus very much resembles the preceding one. The body is of the same shape, and the fins are similar, with the exception of their terminal lines. The general air of the fish is different, however; and, if the expression may be used, there is a softness of character about it which the former does not possess.

There is only one species, though we believe the old and the young, which differ in colour as well as in size, have been described as two. This species is *Mustelus levis*—"the smooth weasel fish," though we believe that the Romans applied the term *mustelus* to any fish that was long and lank like a weasel, and at the same time very voracious. This fish is found occasionally upon all parts of the British coasts, but not, generally speaking, in great numbers. As is the case with all the fishes that hatch their eggs internally, it has no occasion to come to the shallow water for the purpose of spawning, but only in pursuit of the fishes upon which it feeds. It gets various names, such as "the smooth shark,"—"the skate-mouthed shark,"—and "the smoothed hound;" all of which are partially descriptive. It has been remarked, in the case of various land animals, that there is a relation between the armature of the mouth and the character of the skin. The bats, or hairless dogs, which are found in Egypt, have the teeth deficient; and, whether there be any deficiency in them or not, we find that the teeth and the economy of the skin have a sort of common character, which cannot be mistaken by any one who has paid even a little attention to the subject. No one, for instance, could mistake the hair of a carnivorous animal for that of a herbivorous one, or the reverse; and it is exactly the same in the case of feathers. There are physiological reasons why this should

be the case, but this is not the occasion upon which to enter into the particulars of them. They are very valuable, however, inasmuch as they make one part of an animal the index to other parts, and thus greatly abridge the labour of learning. On this account it is gratifying to find a confirmation of this in the inhabitants of the water as well as those of the air. Nothing can be more clear and striking than the illustration afforded by the comparison of this shark with those sharks which have the teeth trenchant. The teeth here form a sort of pavement, with only small tubercles, directed inwards; and the skin is not merely smooth when the finger is passed along, but it is soft to the touch.

There is still another point of resemblance worthy of being pointed out. Along with the teeth of the rays there is in this fish an approximation to the same character of the flesh. The flesh of this species is certainly inferior to that of the rays, especially the true skate, but it is much better than that of any of the sharks which have even the most simple form of the true shark's mouth. It is probable that the character which the sharks have may operate in making their flesh feel less palatable than it would do if there were no such opinion abroad concerning them. We are told what a shark eats, and therefore the idea of a cannibal at second-hand mixes itself up with that of a shark-eater; and as shark is the family name, all the members of the family, whatever may be their food or their manner of feeding, come in for their share of the prejudice; and by this means, on all parts of the coast where the terrible history of the shark is known, there is a prejudice against such a fish as the present species; and it is only in the remote isles, where the people know little of general histories, and are thus thrown upon the judgment of their own senses, that the flesh of the smooth shark is esteemed as an article of food. It so happens, too, that the fish is most abundant in those situations.

This fish inhabits farther down in the water, and lives upon different food from the typical sharks. Its mouth is a crushing mouth, not a cutting one; and, accordingly, it keeps near the bottom, and feeds chiefly upon crustacea. As is the case with the tope, the young, though produced alive, are all produced at nearly the same time, which is about the middle or toward the end of autumn, according to the situation of the place. When this operation is performed, the fishes quit the shallows, or, at all events, do not verge so near the surface as during the summer; but they make their appearance again in the beginning of that season. They are not very prolific, for it is understood that the average brood is not more than from twelve to fifteen.

In this genus we could have many relations, for the fish holds a sort of intermediate place, or, according to the phraseology of the day, it is "a connecting link." This phrase is inaccurate; for the fish is "connected," not "connecting;" but it is used by the initiated only, and of course it cannot mislead them. The fish feeds at the bottom, and does not range the free waters; therefore, though it does not come to the shores to spawn, it comes up to the air and light for the maturing and hatching of the eggs; whereas the sharks that range near the surface find the action of the air and light there; and when they come to the shores, it is only, or chiefly, for the purpose of feeding. This fish does come, and therefore,

though not to such an extent as the spawners, it is a seasonal fish, much less discursive in its every-day habits; consequently it does not stand in need of the firm skin or the tough muscular fibres of those that dash across the breadth of the ocean in quest of their food.

Specimens of five or six feet in length are occasionally taken on different parts of the coast, but in general the fishes are smaller, as the largest ones keep much out at sea. In these there is a farther resemblance between them and the rays. The teeth of the young are without any very elevated points, and thus not well adapted for swallowing a large morsel; but, as they increase in age, the posterior angles of the teeth become more elevated; so that, while they were formerly fit only for bruising a crust, they are now fit for swallowing a fish. The colour of the upper parts and the fins is pearl grey, and that of the under part dull yellowish white. The very young ones have the portion above the lateral line marked with numerous circular white spots; they become fainter and fewer as the fish increase in size; and in very large, and old ones, they are nearly, if not altogether, obliterated. It is these differences which have caused some to describe the spotted one as one species, and the grey one, without spots, as another. This fish is pretty generally distributed over the European seas.

NOTIDAMUS. The species of this genus, of which there are two in the Mediterranean, and some in the Indian seas, are often termed "grey sharks" from their colour, and they have sometimes been confounded with the smooth shark, which favours the preceding genus. The generic name means "dry-back," which is understood to have been the old Greek name for a shark, but whether for these by way of eminence, has not been ascertained. In most respects they so much resemble the smooth shark, that an enumeration of particulars is not necessary. The chief ones are the absence of the first dorsal in this genus, and a greater number of gill-openings. They do not belong to the discursive sharks, and have not, we believe, been found straggling so far as the British isles.

The two Mediterranean species are as follow:—

N. griseus. The grey shark, called also the low shark. It has the muzzle depressed and rounded like that of the white shark, triangular teeth in the upper jaw, and serrated ones in the under. It has also six gill-openings, whereas all those that have been previously mentioned have five only. The colour of the upper parts is ashen grey, and that of the under parts whitish.

N. cinereus. The pearl-grey shark. This one has the muzzle very sharp pointed, as it is in the porbeagle; the teeth, both above and below, are like the under teeth of the preceding species; and there are seven gill-openings of very large size.

SELACHUS.—This name was applied by the Greeks to the whole of the cartilaginous fishes, and is supposed to have alluded to the general uniformity of the surface, which, not being broken by scales, shines while the fish is moistened by its mucous application; and probably the reason why the sharks were called a dry-back was the roughness of their granulated covering. Be that as it may, the fishes of this genus are very different in their dispositions from the true sharks. The generic characters are: the general shape of the body resembling that of the true

sharks; temporal air-holes; gill-openings five upon each side, and so very large that they almost surround the neck; they are placed wholly in front of the pectorals; the teeth small and conical, not serrated in their edges or with lateral tubercles; all the fins present. There are probably more species than one; but the distinctions of them are not known. The one which is known is

The basking Shark (S. maximus). No fish deserves its specific name better than this one; for though, in as far as accurate information goes, it is both maximus and minimus in its own genus, it is *maximus* among the whole of the fishes, being larger than any known inhabitant of the deep, excepting the *Cetacea*. It is a fish of the more northerly parts of the Atlantic, although not exactly of the polar ones; but it ranges to considerable distances, and occasionally finds its way as far to the north as the Bay of Biscay. On the western coasts, especially among the Hebrides and toward the north-west of Shetland, it is a common fish in the summer months; but it goes out to sea in the winter. It swims high in the water, so as to display the dorsal fin which is of considerable size, and as the fish does not tumble along like the porpoise, but swims smoothly, and at times remains basking in the same spot as if it were becalmed, it has got the name of the "sail fish." In sailing or rowing about among the western isles in the summer months, where such an occupation is so very pleasant, one is never long without seeing the fin, and sometimes a portion of the back of the fish rising over the water. It is also as mild and unsuspecting as it is conspicuous; so that, if it is basking, one may row close to it, and even touch it, nay wound it, if the wound is not severe, without its apparently taking much heed of what is going on. If, however, this wound is deep and severe, the fish is instantly roused, and dashes off with so much velocity that, if the wound is inflicted by a harpoon, those in the boat must stand clear of the line, and be careful of the boat itself, as, if it is an ordinary skiff, it is liable to be upset. The flesh of it is not eaten; but the liver yields so much oil, that a large fish is a prize to the captors. Any thing equal to or exceeding thirty feet in length is accounted a large fish; but there are accounts of some reaching little less than forty.

Though this fish makes its appearance regularly and in numbers on the coasts that have been alluded to, and though there are few parts of the British coasts where it is not occasionally to be met with, yet very little is known of its feeding or its manners. It does not appear to follow any of the shoaling fish for the purpose of feeding on them; and therefore it has been supposed to feed chiefly on the floating mollusca and on crustacea. It is ovoviviparous; but the rate of its productiveness has not been well ascertained. The colours are: clouded brown and blue on the upper part, and bluish-white on the belly; the body is spindle-shaped, thickest at nearly the middle of the length; the head is conical; the muzzle rather blunt and very short; the opening of the mouth much more nearly in the plane of the body, and the jaws much more nearly of equal length than in the more ferocious members of the family; the eyes are situated near the snout; they are small, of a brown colour, and longer in their horizontal diameter than in the vertical; the nostrils are lateral, there being very little projecting snout for them to be placed under; the pectoral fins of moderate size; and the

first dorsal, notwithstanding its sail-like appearance, not large, considering the size of the fish; all the other fins are well formed, but not large; the caudal forked, with the two lobes divergent, and nearly equal in length; the tail near the base of the caudal keeled laterally, and grooved on the upper and under sides.

Perfectly harmless as this huge fish is to man, and apparently to every thing in the sea upon which man sets a value, it is a subject of very great alarm when it appears upon a part of the coast where it is but little known. It is a shark in name, which appears to be sufficient ground for investing it with all the terrors of the tyrant of the sea. We have known instances where the rumoured invasion of a shark put all the people in motion, and the timid were apprehensive that the "monster, whose terrible fin could be seen from the beach, would swallow men, boats, and all." But the more adventurous who embarked to avert the destruction rowed close up to the fish, soon despatched it and towed it to the beach, where, after the liver was abstracted, the spoils of the portentous spoiler remained there, testifying to more senses than one how well the natives could defend themselves against invasions of sharks. There might have been another prop to their prowess; for at that particular time they were girt with weapons against another kind of invasions in which the eye of reason saw about as much real danger as even that by the basking shark.

CESTRACIONUS.—Of this genus only a single species is known. It is a native of the Australian seas. In its characters it appears to be intermediate between *Mustelus* and *Spinax*, having teeth like a pavement in common with the first, and a spine in the anterior part of each dorsal like the second. Nothing is known of this genus that could in the least interest the reader.

SPINAX.—This is a genus with which we are better acquainted, as there is one species which is not only common, but exceedingly numerous on some parts of the British shores. The characters of the genus, in brief, are: the body elongated; two dorsal fins with a strong spine in front of each, united to the edge of the fin at the base; no anal fins; temporal orifices; the teeth in several rows, small, and with cutting edges; the gill-openings small, close together, and all in advance of the pectorals. The British species, and indeed the only species which is very well known so as to be interesting to the general reader, is

The Piked Dog-fish (S. acanthias). This is the Scotch name of the fish, the English one on those parts of the coast where it is most abundant, being the "bone-dog," which is also in allusion to the spines. "Pyked" is the proper pronunciation of the epithet, and though this is from the same radical word as "pick," yet the senses in which they are now used are not the same; and thus even Mr. Yarrell, following the false orthography of some one else, has spelled the name "picked," which, as we use it, means "selected," whereas, if he had just left out the c, and written "piked," there would have been no need of telling that "pike means pike."

This fish is much more abundant on the British coasts than any of the other *Squalida*; and in the northern parts where the genus *Scyllium* is hardly known even now, it has been the "dog-fish," and the "sea-dog," time out of mind.

It is a small fish compared with many others of the family, but it is a very bold and active one, and well

organised both for swimming and for using its teeth. The length of what are usually considered full-grown ones is about three feet; but the majority that appear are smaller. The general shape of the body is not unlike that of the tape; but there is an expression of greater vigour about it. The head is flat with the temporal orifices large and upwards; the snout produced, but rather blunt; the nostrils pierced in the under part; the gape wide for the size of the fish, and opening to a circle as in the sharks; the teeth pointing outward on each side, and with sharp cutting edges; the eyes lateral, the horizontal diameter the longest; the pectoral fins large, triangular, convex before, concave behind; the ventrals much smaller, and the anal entirely wanting; the two dorsals divide the entire length from the snout to the tail very nearly into three equal parts; these last fins sloping backwards, and slightly convex in their anterior margins, rounded at the tips, concave backwards, with a narrow lobe at the base of each; the spines in front of the dorsals strong and very sharp-pointed, the first rather more than half the height of the fins, the second the whole height; the upper and under lobes of the caudal forming a rounded terminal fin, but with a triangular lobe of the under one opposite to about the anterior half of the upper; the upper part and also the fins slate-grey, the under parts yellowish-white; the skin rough when the hand is passed forward over it; the fins granulated and used for polishing wood, as are the fins of many of the family, the "grain" on them being finer than that on the body.

There is, we believe, scarcely any part of the country where the flesh of the dog-fish is eaten in the recent state; and there are few fishes which the fisherman are less fond of seeing in numbers on the fishing-grounds. The numbers in which they appear are almost incredible. They are on the coast early in the season, and they remain till it is late, so that they attack all the more valuable fishes when they shoal toward the land. From the tendency which they have to associate in immense packs they are seldom found along the whole line of the coast, but they alarm the fish, and drive them from the grounds. Their bite is powerful and their gape wide, and thus they swallow and mangle vast numbers. It is also understood that they get below the fish and wound them with their dorsal spines. The command which they have over these weapons is very great; they can work them with the whole muscular power of the body, and strike with wonderful rapidity and certainty. It is not safe to tamper with them after they are taken, for, like all the rest of the family, they are very tenacious of life; and, when lying apparently lifeless, they will start into action and inflict wounds with the spines.

Besides the injury which they do the fishers in driving the fish from the grounds, they watch the lines and cut off such fish as are caught; so that even after the lines have been filled, a large pack of sea-dogs coming on the ground will leave the owners to draw them in empty and hookless. Mr. Couch mentions that he has heard of twenty thousand being taken in the sea at one time, among which, however, there must have been a great number of young ones. The livers afford a good deal of oil; and in those northerly places where the people depend so much on the sea for their subsistence, and the sea is in a great measure inaccessible or unprofitable in the winter, their flesh is salted and dried. It is rather

hard and tasteless ; but still it is better than absolute hunger. Then, when they are abundant, the offal is of use in enriching the fields.

CENTRINA.—This genus have spines on the back as well as the last, but the one is directed forwards and the other backwards. They have several rows of small pointed teeth in the upper jaw, and one or two rows of cutting teeth in the lower ; they have the tail very short and the body massive, a sort of triangle in the section, the lower part of the fish forming the base of the triangle ; they have the habit of lurking in the mud at the bottom, for which reason they are sometimes called sea-hogs. It is probable that, while they lie in this manner, they wait for prey, which they first wound with the dorsal spines, and then seize with the mouth. They are found both in the Mediterranean and the Atlantic ; but there is no mention of them even as stragglers upon the British coasts. They are fishes of little interest, as they are of small use, and do less harm than the dog-fish. In consequence of their lurking habits, they are seldom caught or even seen.

SCYMUS. Some species at least of this genus are better known and possess a higher degree of interest than the preceding one. In the characters of the mouth they are nearly the same, having several rows of sharp-pointed teeth in the upper jaw, and two rows of cutting ones in the under ; the first dorsal fin is placed near the middle of the length of the body ; there is no anal fin, and the tail is rather short. Some species of this genus occur in the seas of the southern hemisphere, and there is one in the north, which is a large and powerful fish, and among the most polar in its locality of any of the shark family. This one is

The Greenland Shark (S. borealis). This has been named in the lists as a British fish, but on very slender grounds ; for the two that have been mentioned did not come even as living stragglers, but were cast on the shore. Farther to the south it has never been observed, even in the state of a wreck, drifting before the current of the water. Its colour on the upper part wants the brownish tinge, but otherwise it is not very unlike that of the great white shark of the warm latitudes ; but the shape is like that of the prehensile. In consequence of the similarity to the white shark, when seen at a distance, this Greenland one was long considered as being either the same or a variety ; and thus, though it is a large and powerful fish, it has got a character for voracity which it probably does not deserve to the full amount that has been stated.

The best, and indeed the only good account of the Greenland shark which has been given from actual observation, is that in Scoresby's work on the Arctic Regions, which we shall quote :—"The *Squalus borealis* is twelve or fourteen feet in length, sometimes more, and six or eight feet in circumference. The opening of the mouth, which extends nearly across the lower part of the head, is from twenty-one to twenty-four inches in width. The teeth are serrated in one jaw, and denticulated in the other. It is without the anal fin, but has the temporal opening ; the spiracles on the neck are five on each side. The colour is cinereous grey. The irides are blue ; the pupil emerald green.

"This shark is one of the foes of the whale. It bites and annoys it while living, and feeds on it when dead. It scoops hemispherical pieces out of the

body, nearly as big as a person's head ; and continues scooping and gorging lump after lump until the whole cavity of its body is filled. It is so insensible of pain that, though it has been run through the body and escaped, yet, after a while, I have seen it return to banquet on the whale, at the very spot where it received its wounds. The heart is very small ; it performs six or eight pulsations in a minute, and continues beating for some hours after taken out of the body. The body also, though separated into any number of parts, gives evidence of life for a similar length of time. It is therefore extremely difficult to kill. It is actually unsafe to trust the hand in its mouth, though the head be separated from the body. Though the whale-fishers frequently alip into the water where sharks abound, there has been no instance, that I have heard of, of their ever having been attacked by the shark.

"Besides dead whales, the sharks feed on small fishes and crabs. A fish, in size and form resembling a whiting, was found in the stomach of one that I killed ; but the process of digestion had gone so far that the species could not be satisfactorily discovered. In swimming the tail only is used ; the rest of the fins, being spread out to balance it, are never observed to be in motion but when some change of direction is required."

There is the foundation of much knowledge in this passage ; and if the other inhabitants of the deep could be examined as closely, and described as well, our knowledge of fishes would assume a very different character from what it has at present.

Insensible as the Greenland sharks are to pain, and formidable as they are to the whale, they are not without their enemies, of a description against which their powers are not of the slightest avail. Captain Scoresby found attached to the eye of the shark a white worm-shaped substance about two inches in length, terminating in two filaments. On examination this was found to be a species of *Lernæa*, a parasitical zoophite, various species of which torment fishes by attacking their gills, their eyes, and other delicate parts of their structures.

There appear, from the reports of naturalists who have visited the South Sea, to be sharks there which agree with the Greenland shark in some particulars, but differ from it in others.

ZYGÆNA.—Yoke-headed or hammer-headed sharks. These have many of the characters of the genus *Carcharias* ; but the form generally is very unlike them, and the head is so singular as to have no parallel in the whole animal kingdom, many and varied as are its members. These curiously-formed fishes appear to be widely distributed, being found in the seas both of the north and the south ; and one specimen is recorded as having been taken at Yarmouth in 1829. Four species have been described, and there are probably many more, but we must confine our notice to one.

The common hammer-headed Shark (Z. malleus). This species grows to the length of twelve or fourteen feet. The body is rounded in its section, spindle-shaped, with the thickest part behind the first dorsal fin, and the tail very long ; the pectoral fins are large, originating immediately in the rear of the last gill-opening, convex on their anterior margins, concave on their posterior, and pointed. The first dorsal is nearly opposite to them, of considerable size, and with a deep curved notch in the extremity.

The ventrals are nearly midway between the pectorals and the anal, of moderate length in the first part, but shortened posteriorly. The second dorsal and anal opposite to each other, the first rhomboidal, the second with a deep curved notch in the extremity. The caudal longitudinal, in the upper and under sides of a very long and rounded tail, the two lobes meeting and forming a lancet-shaped tip. The upper lobe very low and of uniform height; the under rather broader, with a fulcate prominence at the commencement, and a portion near the tip a little enlarged.

Hammer-headed Shark.

The most singular part of the structure, however, remains yet to be noticed. The body, which tapers from midway between the pectoral and ventral fins, continues in a lengthened and comparatively slender neck; then the head has the snout truncated in front; but the head itself is drawn out into two branches at right angles to the axis of the body, nearly of the same thickness as the neck, and altogether not unlike a double-headed hammer, with an eye in the middle of each face, and directed at right angles to the axis of the body. The nostrils are in front of these curious branches, and the mouth is at the middle of their length below. The outlines of the fish are remarkable for the gracefulness of their curvature; the neck and the two lateral branches of the head appear to have great power of motion, and the whole air of the fish is expressive of velocity and energy. What particular purpose in the economy of the fish is answered by the eyes being thus placed on peduncles, has not been ascertained; but there is no doubt that a necessity for such extended vision as this strange organisation can command accompanies the organisation. In farther confirmation of this, the eyes themselves are large and prominent; so that, taking the whole together, there is really no animal that commands so extensive a field of view. The teeth are large, formed and serrated like those of *Carcharias*; and there are at least three rows in each jaw. It is a very discursive fish, found in the deep water rather than near the land. It is said to be exceedingly voracious and daring, scarcely less so than a white shark of the same dimensions. Its food is said to consist chiefly of the rays; and as they are exceedingly active fishes, it requires all its powers, both of vision and of motion. A full-grown one weighs four or five hundred weight, and the liver yields a great deal of oil; but the fibres of the flesh are very rigid, and unfit for food.

SQUATINA—Angel-shark or Monk-fish. This is the third of the leading genera into which Cuvier divides the family of the *Squalidae*. The generic characters are: they have temporal openings, but no anal fins; the body very much depressed, and the head rounded at the snout, and very broad and flat; the opening of the mouth in front of the muzzle, and the eyes in the upper surface of the head, and not lateral, as in the greater part of the family; the pectoral and ventral fins so large that the outline of the body resembles that of the rays. The fish of this genus are, however, independently of their more scientific differences, easily distinguished from the rays by the form of the disc or flattened part itself. In the rays, especially in what may be, and are, called the true skate, the disc is composed of the pectoral fins only; and in the thornback, the starry ray, and some others, in which the ventrals form part of the line, that part is so little in comparison with what the pectorals form, and so easily understood to be a mere supplement, that one can easily see it in its proper light, and look upon the great breadth of the fish as produced by the enlargement of the pectorals only. Even in the torpedo, where the ventral fins are more produced than they are in almost any of the others, the fact of their being only supplemental to the body of the fish is apparent upon mere inspection. But in the genus *Squatina*, though the pectorals are much larger than the ventrals, they form an integral part of the body of the fish, and not a supplemental one. The character of the head also is not to be mistaken; for there are none of the rays which have a rounded muzzle with the opening of the mouth at the extremity. The only species of which we can find room to give a few particulars is *Squatina Angelus*—the Angel-fish, Monk-fish, Shark-ray, and a variety of other names. How it came by such a "commodity of good names" as it has obtained is a matter of some little astonishment at this time of day, and when we carry back our consideration our astonishment increases. Though the association of any material form, however admirable in itself, with the proper notion of an angel, as an existence of a spiritual and ministerial nature, and as such having nothing to do with form, be a very palpable and most unphilosophical absurdity, yet, if we will speak of an angel in tropes and figures borrowed from material forms, it behoves us to select something for our symbol which at all events is not repulsive. But taking it in its mere appearance, without any reference to its manners, which are certainly not the most angelic, this angel-shark is about the ugliest fish that the sea contains. True, the pectoral fins of the fish have some resemblance, and a very slight resemblance it is, to wings; but granting that it were not the mere resemblance, but the most perfect wings that ever were grown of material substance, what have wings to do with our notion of an angel? Wings are for overcoming the gravity and motion of matter, and for no other purpose; and if they are essential requisites of an angel, then that angel is a material creature, and consequently no angel at all. It is true, that we use the word "wings" in these cases; but all that we mean is, that there is a velocity or a power of velocity which we cannot trace farther than that which displays, or is capable of displaying, the said velocity.

This fish is occasionally found on various parts of the British coasts, most frequently on the south, but

occasionally on the east, though not very far to the north. Its proper home, that is, the locality in which it is most abundant, is the Mediterranean, where it has been known since the days of Aristotle, who called it the "file," probably on account of the roughness of its granulated surface. Its form indicates a very different habitat from that of most of the *Squalidæ*; and any one in the least acquainted with the structures of fish, and the localities for which their structures are adapted, would at once say "this is a bottom fish, an inhabitant of the bank." It would of course be in vain to look for such a fish on the rocky shores, where the water is deep and clear. The banks where tides and currents meet, where there is a constant accumulation of animal matters, and abundance of flat fish, are the places where to find this "angel of the deep," in the home of its enjoyment.

It is well adapted for the office which nature has assigned it. It grows to the length of seven or eight feet, and is very muscular. The division of each of the produced lobes into two by the fins is an advantage in swimming which the flat fish, and even the rays, which have the principal lobe single, do not possess; and thus it is admirably fitted for beating its prey in their own kind of swimming. When it attains the largest size, it is a very heavy fish, not less than 150 pounds in weight; and this, with the quickness of its swimming, enables it to impinge with great force on its prey. Then its eyes and mouth are adapted for forward chasing; the depth at which it preys is not too great for the view, and the broad mouth and wide gape are ready to dine on a turbot, even of very considerable size. The rays are usually set down as among the articles of food consumed by this singularly ugly fish; but we have some doubts as to this part of its bill of fare, more especially in the case of those rays that have formidable spines on the tail. Indeed the following up of these spiny rays to take them in the rear would not be a very pleasant business even for the fish, clad in armour as it is. Besides, the rays feed chiefly on what is under them; and this is rather against their being a common prey to this species, though the peculiar structure of the hammer-head fits it for seizing them with the greatest certainty. This fish is so peculiarly formed, and so powerful, that it would be very desirable accurately to determine its place and function in nature, but at present the data are far from complete.

We have already mentioned the size which this fish attains. The body of it is formed something like a tadpole; that is, the head is, if the lateral fins are not taken into the estimate, so far wider than the body, and the body, the distinction between which and the fins is much more conspicuous than in the rays, is cylindrical, or has the sides parallel from the head to the first dorsal, and then it tapers gradually to the tail. The plane of the head is nearly circular; the eyes far apart, though both on the upper surface; and the temporal openings are behind the ears, large and crescent-shaped. The anterior margins of the pectorals touch the sides of the head, about the middle of their lengths, so as to leave about a semicircle of the outline of the head free. After this they diverge in nearly straight lines, at rather less than a right angle, until their distal extremities are nearly as far asunder as from the mouth to the first dorsal. They return in lobes nearly at right angles to their front lines, and then return rounded, overlapping the anterior and external edge of the ventrals. The ventrals ex-

tend as far as the first dorsal, projecting beyond the lobes of the pectorals anteriorly, and slightly bilobate in their posterior margins. The general form of the disc is thus nearly a rhombus, but with the posterior sides deeply notched between the pectorals and ventrals, and the anterior ones very slightly between the head and the pectorals. The tail is nearly as long as the body from the head to the first dorsal, bearing the two dorsals, and a caudal of two triangular lobes, one on the upper side and another on the under. The opening of the mouth extends nearly along the whole semicircle from the one dorsal fin to the other, so that the gape, when at its full extent, is circular and very wide. The upper part is shagreened with tubercles, and there is a row of spines along the dorsal line, which are said to be much more prominent in some than in others. The upper part is mottled with brown and greyish, and the under part dull white. It is ovoviviparous, and the young, to the number of about a dozen, are all produced about the same time, as is usual in the members of the family which are not very discursive. The flesh, like that of the others, is hardly edible, and thus the fish is not sought after. It is not so much disliked as the species which feed nearer the surface, as it interferes comparatively little with the fisheries. Hence it is allowed to enjoy its splendid name, and feed its very unhandsome carcass quietly in the deep.

PRISTIS (Saw-fish). This is also made one of the leading genera by Cuvier, and it is the last of the family in the order of his arrangement. There are several species, but this article has already extended to such a length, that we can notice only one as a specimen of the general appearance and habits. The generic characters are: the same physiology as the rest of the family; they have the anterior part of the body flattened, and the gill-openings pierced below, as in the rays, and their teeth are small and round, like those of the smooth-hound. The most remarkable of their character, however, is the form of the muzzle, which is lengthened into a very long weapon, formed like the blade of a sword. This weapon is furnished on each side with a row of very large and strong teeth, standing at some distance from each other, and forming altogether one of the most terrific weapons that can well be imagined. The species which we shall notice is

The common Saw-fish (P. antiquorum). This fish has been known from remote antiquity as one of the monsters of the deep, and the present generic name is the one which was given to this species by the Greeks. This fish is more generally distributed than almost any other; but it is a fish of the high seas, and rarely, if ever, makes its appearance on the shores. It is found on the margins and in the openings of the polar ice, and probably it passes freely under the fields and floes; it is also found under the equator, and equally in the southern seas and the northern. It thus, in all likelihood, passes purely along the same latitudes as the British islands; but not a single specimen is mentioned by the authorities as having occurred on any part of the coast. The colour of the saw-fish is very dark grey on the upper part, passing into ashen-grey on the sides, and nearly into white on the middle of the belly; the skin of the upper part, excluding that of the lengthened snout, is covered with hard tubercles, with their sharp points turned backwards; the covering of the snout with these would make it a very serious weapon, from the

ragged wound that it must inflict; but they are nothing compared with the teeth with which the sides of the back are beset; they are large and strong, firmly rooted like teeth, and about eighteen or twenty on each edge of the back; the point of the blade is not sharp; and, in fact, the whole weapon is one fitted for tearing and mangling rather than for simply wounding. Of course such a blade must be moved with great force before it can do its work; and the fish is well favoured for effecting this; it attains a great length; and as the first dorsal and the very large pectorals are placed on nearly the same part of the length, it can swing upon them in every direction as upon a universal joint, and so deliver its weapon in any quarter where it may have the greatest effect. This, and not the sword-fish, which is a bony fish of the mackerel family (see *SCOMBRIDÆ*), is the fish which is so mortal an enemy to the whale, in company, as is said, with the fox shark, but we believe that, far to the north, it is with the Greenland shark. The weapon of the saw-fish is, in the very large ones, about six feet long, and the animal can plunge it into the body of a whale the whole length. Nor have we any reason to doubt that, when the fish takes a rush from a distance, in order to deliver its weapon, it has force enough to accomplish this, for it sometimes runs the snout into the timbers of a ship in the same manner as is done by the sword-fish.

Saw-Fish.

It is probable that this one uses the sword for the purpose of killing, in order to eat; for, though the saw-fish could no more swallow a whale than the sword-fish, yet it has powerful teeth, and could bite off pieces, an operation for which the toothless mouth of the sword-fish is not at all adapted. It should seem, therefore, that whenever the stabbing of the Greenland whale by any ferocious fish is mentioned, the present species, and not the sword-fish, should be understood. This understanding gets us out of another difficulty. In all such accounts of battles as that related by Captain Crow, of which some account will be found in the section *Sword-fish*, as above referred to, it is stated that the stabbing fishes are in numbers; whereas, even in our seas, it arrives only singly, and that but rarely; nor is it for feeding in concert that sword-fishes congregate. All the *Squalidæ* hunt in packs; and thus, whether the object of their hunting be a whale, or anything else, we may expect them to follow the general law of their family.

Such is a very brief outline of the shark family, one of the least valuable, in so far as human food is concerned, of any that are to be found in the sea; but, taken as part of wild nature, and as showing the power and the beauty with which created things are adapted to the end which they are appointed to accomplish, one of the most instructive that can be made the subject of human observation and reflection.

SHEEP (*Ovis*). A genus of ruminating mammalia with horns, placed, in Cuvier's arrangement, after the goats, and before the oxen, but having far more resemblance to the former than the latter. It has,

indeed, been pretty generally alleged that sheep and goats not only can produce, but actually have produced, a mongrel breed, which continues fertile as well as either of the races which are blended in its formation. It must not, however, be supposed that, in the "*Règne Animal*," Cuvier actually asserts that the mules between the goats and sheep continue fertile in the mixed blood, so as to obtain a flock, a breed, in which the qualities of goat and sheep shall be blended together. His words are, "*Ils (the sheep) méritent si peu d'être séparés génériquement des chèvres, qu'ils produisent avec elles des petits féconds.*" This is true, and we may add, that whenever any two species of animals are so nearly allied in their structures and their modes of life, as to produce a hybrid at all, that hybrid is always fertile. But it is fertile to return to the pure blood only, and not to remain in the same state of mixture from generation to generation. We must not, however, seek for any distinctions founded on the production of animals, beyond these three; first, that the race continues, without any return to another species; secondly, that there are mules which will only breed back again; and, thirdly, that there are cases in which no mule is or can be produced. Taking this as the foundation, the first of these would determine what were the same species; the second what were not the same species, but the same genus; and the third, what were different genera. If this could be established in all cases, and referred to at all times, there is no doubt that it would be an excellent foundation for a systematic arrangement of the animal kingdom. But there are no means of doing this in one case out of ten thousand; and therefore, though we may appeal to it in common cases, it is really of no value whatever. The distinction between genus and genus is not founded in nature. It is an application of art which man makes, in the hope of thereby shortening the road to knowledge—whether he always does so by means of it is another matter. It is thus quite clear that the greater part of our systematic distinctions must be purely artificial; and all that we have to do is to take care not to impute to nature that which is our own doings; for we may appropriate nature to ourselves without the slightest injury.

But, to return to our subject, sheep have been broken down into such a number of breeds by artificial means, that is, by climate, food, and attendances, that we cannot help admitting that they may have been to a very great extent changed by nature in the same way; and though, of the few races of them that still remain in a state of nature, those which have their pastures very different, in a physical point of view, are themselves different, yet they may have been all originally from the same stock. It would, however, be a waste of time to go further into the details of this part of the subject, than the statement of the principle to guard against positive assertion, where there is or can be no real knowledge. The generic characters of the sheep are founded on its structure, which is open to all, and not on its physiology, which is more limited. In this simple and popular view of it the following are the characters usually given: the horns angular in their erection, furrowed across, bent laterally into spirals, and formed upon a cone of spongy bone, which, as far as it goes, takes the form of the horn itself; the teeth are in all twenty-two, eight incisors in the lower jaw, and six grinders above and below on each side; the incisors form a regular

arch, the number of which are placed neatly and compactly together, the two next the middle being the largest, and the others becoming less and less as they are nearer the sides; the line of the forehead is arched; the muzzle is without any naked part; the nostrils elongated, oblique, and terminal; and the chin is without any beard; the ears are of mean length and pointed; the body of middle stature, warmly covered with hair; the legs are slender, and without any brushes on the knees; the females have two inguinal teats, but there are no pores in the groin; the tail is generally short and pendent.

Generic characters of the sheep can hardly, however, be so expressed as that they will be perfectly applicable to any one of the great number of breeds into which the genus has been broken; and thus, though every child knows a sheep from any other animal at first sight, it is not quite so easy a matter to say why it is a sheep, and not a goat or something else. In order to be quite clear upon such matters as this we want information respecting the reversed operation. We know that certain stocks may be broken into sections, but we have very little knowledge as to how these sections may be put together so as to get us back the original stock of which they were broken. It is true that, when plants or animals that once have been changed, or as we say, according to the notions which we have of them, improved by artificial means, are neglected, they become very inferior to what they were in the cultivated state; but we cannot assert with truth that they return to the original. If they are very highly cultivated, that is, brought very far out of their natural state, and then abandoned to the contingencies of wild nature, they are apt to perish entirely. This seems to have all along been the case with the cereal grasses which mankind have cultivated for their bread corn. There is no reason to doubt that all of these have been cultivated out of wild grasses; and it is very unlikely that all the wild grasses out of which they have been cultivated should have perished. Of several of the millets, and the *raggy* of India, as well as various others of the inferior sorts, the originals are still to be met with in wild nature, not very different from the cultivated ones; but we look in vain for any wild plant which we can with certainty say once was, or hereafter is to be, wheat or barley; and the same may be said of many of the more valuable luxuries.

Animals being more removed from the state of mere matter than plants—less completely in the power of man, as clay in the hand of the potter, than plants—cannot be so much changed by human art; but still there are several of them of which we cannot find in wild nature any thing that we can absolutely say is the original. This is the case with the dog, the horse, and the ox; for though there are wild animals still to be met with, with which some at least of these can have fertile progeny, yet we cannot say that they are the species out of which the domestic one has been cultivated.

It is probably the same with the sheep. The sheep, notwithstanding the influence which cultivation has had upon it, is not nearly so domesticated an animal as the ox; and, therefore, there are wild sheep which resemble the cultivated sheep much more than any of the wild oxen resemble the cultivated oxen. But still this resemblance, or the fact of their having fertile progeny with each other, must not be hastily

taken in evidence that the ones which are now wild are the stock out of which the cultivated ones have been bred. Of late it has been ascertained that the wild sheep of the mountainous parts of the Mediterranean islands will breed with tame sheep; but this fact has not been ascertained long enough for enabling us to decide whether they will remain as permanent races or not.

The wild sheep which are still to be met with are found in the mountainous parts of the great lands in the northern hemisphere; but it does not appear that there are any in the south—in South America; in Africa, south of the Great Desert; in Asia, south of the Himalaya; in the Oriental Archipelago; or in the isles of the Pacific, except the very northerly ones. Thus it should seem that they are originally and properly animals of the northern hemisphere; and the places in which they are found point out the physical circumstances of what may be considered as their country. They are decidedly mountain animals, but not scrambling among the rocks as the goats are; and although they are placed differently in the systems, it appears that their proper locality is between the goats and the antelopes, though in the countries where antelopes are most numerous, there are no wild sheep, which has led to the placing of them between the goats and the oxen. The goat on the pinnacles where the patches of herbage are small and of difficult access, the sheep on the breadth of the dry upland pasture, and the ox in the valley or meadow by the large river, are the places of the three in nature. In their food, and the manner of taking it, they all very much resemble each other, for they are all grazing animals; but a goat can eat vegetables which are poisons to the other two, and a sheep can find its food where an ox would starve. On the other hand, a goat would be very much out of its element in the humid pasture which the ox prefers; and a sheep would soon become diseased in the feet and unable to seek its food. The sheep too, even in the cultivated races, must, in order to be profitable, have a much greater breadth of pasture than any of the other two.

There is another result of the comparison of these three genera of the *Ruminantia*—all things considered the most valuable to man in the whole animal kingdom, which should not be overlooked, because it points out the situation in which each may be introduced with the greatest advantage. The rocks of the goats, and the plains and meadows of the oxen, are both liable to sudden rains; and the coverings and also the constitutions of the animals are such, that the rain does them comparatively little injury. The hair of the goat throws off the rain as if there were absolutely a repelling power in it; and even when the goat is, like the shawl goat of the northern slopes of the Himalaya, provided with a close wool on the skin, there is always along with it a sufficient quantity of long hair of a smooth and shining surface to throw off the rain and snow. Sheep, in the wild state, are understood to have hair and not wool, though the point is one which does not admit of absolute demonstration; but even then their hair is very different from that of goats; and when the hair of which is laid into wool, unless it be in climates which are positively cold and rainy, the whole hair turns wool without any long and smooth hair to carry off the water. There is also a tenderness in the covering of the sheep, whether that covering be hair

or wool, which is never found in that of the goats, be the staple what it may. No fabric made of wool has nearly the same durability as the shawls that are made of the fine under-covering of the goat of the Himalaya, formerly alluded to; and, on the other hand, the covering of the goat cannot be felted or wetted in the same way that wool can. In consequence of this, the covering of the goats, however long and shaggy it may be, never gets matted, while the wool of the sheep always does, and does so the more the finer it is in the staple. It is this matting which renders the covering of the sheep so liable to injury by long exposure to the rain. It holds out for a considerable time no doubt, and the finer that it is it holds out the longer; but then, when a fleece of this kind is once wet through, it takes a very long time in drying, and the health of the animal is injured by the cold produced by the evaporation of so much moisture as there is in the fleece. We find that there is, in the nature of the animals, a tendency to correct this in so far. If the fine-woolled sheep, whose proper pasture is the dry plains where there are not many rain-storms during the summer, are taken to the hills where the atmosphere is habitually cold and dripping, they in time become comparatively rough in the coat, which is longer in the fibre, but much less matted together. On the other hand, if they are taken to very hot countries the fleece changes in time to thin and coarse hair, as is the case with the sheep in India. All the circumstances, indeed, point out the locality proper for the sheep, as being that which is dry, and neither too cold nor too warm. Oxen, on the other hand, thrive best where the atmosphere is rather moist, because they have a more luxuriant and tender pasture. Goats are more proof against all weathers than either oxen or sheep; and their sure-footedness enables them to reach the patches of herbage in places which are quite inaccessible to both the others. We shall, however, have occasion to make a remark or two upon this part of the subject when we come to notice the leading varieties of cultivated sheep; and, therefore, we now proceed to a mere notice of the wild ones, in which we shall take them as they stand in the system, without admitting or denying that they are different species. In doing this we shall take them in their geographical distribution, without considering any of them as more typical of the genus than another.

THE Mouflon. This one is called the Corsican sheep and the Sardinian sheep, because it is particularly numerous in the mountainous parts of those islands, though not confined to them. It is also called the wild sheep, and supposed to be the parent stock of all the tame breeds of Europe, though of this there is of course no conclusive evidence either way. This species is rather larger; that is, it is a larger-boned animal than the average of the cultivated sheep. The horns are triangular; that is, they present three faces; the first posterior and internal, the second inferior and anterior, and the third superior and anterior. The posterior face is smooth, or without ridges, and larger than either of the others, and it is slightly convex in the first part of its length, but concave in the remaining part. The other two faces are flat for the greater part of their length, but concave for a little space toward the point of the horn. The ridge which separates the two faces of the horn is very prominent, and almost what may be called a cutting edge. The

first curvature is always outwards and inwards, and backwards and forwards. These horns, though triangular in the basal part, are flattened into a sort of laminae or blades toward the points. They are very broad at their bases, and occupy so much of the upper part of the head that they are separated by a space of only about a quarter of an inch, and in some instances their bases meet without any interval. Their average divergence from each other at the base is about a right angle; but it is not quite constant, being sometimes ten degrees more, and at other times ten degrees less. These horns are ridged and annulated, like those of the cultivated sheep, but the annuli are generally closer together, and on the basal part of the horn they are at irregular distances.

The mouflon is covered with two sorts of hair, one woolly, and very fine and soft to the touch, and arranged into curled locks like the wool of the common sheep, and of a grey colour. The other kind is straight and bristly; and from its length it is the only part of the covering which is visible to the eye, and has to be lifted up or aside before the woolly part is seen. The colour therefore depends on this larger and more bristly part of the covering; and, as it is variously coloured, the apparent colours of the individuals vary along with it. In some cases it is yellow, in others black, and in others again it is variously annulated of these two colours. These differently-coloured hairs are generally found on the same individual, but they vary in their proportions; so that, taken on the whole, different individuals of the same flock appear to be differently coloured, the yellow predominating in some instances, the black in others, and others again having every shade that can be produced by a mixture of the two. These colours are not constant, even in the same individual, but change with age and with the season. In winter the colour is more inclining to brown than at other times, and the young are of a clearer and brighter tint than the old. Some individuals are also nearly or altogether white, and others are black. They have very often a black streak along the dorsal line, and not unfrequently another, black or blackish, on the flanks, separating the upper parts from the under; the latter are white, as are also the insides of the legs, the buttocks, a spot under each eye, the middle of the face, and the insides of the ears. The tail is very short, and the sides of it are white. The hoofs and horns are of a yellowish grey, and the latter, measured from the base along the curvature, are nearly two feet in length. The tongue and the inside of the mouth and nostrils are black. The authorities are not quite agreed about the horns of the females: some describe them as having no horns, and others as having them, only smaller than those of the males. The fact of the case seems to be that the females have sometimes horns and sometimes not; but the presence of these appendages seems to be the exception, and the absence of them the rule.

The mouflon has been known from the remotest antiquity, and it is probable that, in former times, it was common in places where it is not now to be found. At that time it was sometimes called the *Ophion*, or "glider," probably from the fleetness of its motions; and Strabo and Pliny describe it pretty accurately as the *Musmon*. Pliny mentions it as being found in the mountains of Spain, and in those of Sardinia, Corsica, and some other of the islands of the Mediterranean, the places where it is still to be

met with; [for some naturalists mention it as still occurring in the mountainous parts of the south-east of Spain.

In their habits these animals have a very close resemblance to the common sheep. They assemble and pasture together in numerous flocks; and so much is this their habit that, if an individual is kept in solitude, it pines away and very soon dies. As is the case with common sheep, this social instinct appears to be the only one which is very strong in them, and they will follow it even to their personal danger. When kept in confinement, they do not appear to acquire any knowledge of persons, so as to be able to distinguish those who feed and are kind to them from others. When food is presented to them, they come to that; but they do not heed the person who is in the habit of feeding them, unless the food is shown. This is very much the character of common sheep, which are far less intelligent than oxen, and do not appear to know either their owners or their homes. Therefore they must always have a shepherd to conduct them, and lead the flock to where it may be wanted; for, although they keep together, the whole would wander off, and never return to the fold, unless conducted.

THE ARGALI. This is the wild sheep of the central and northern parts of Asia, and has been not unfrequently confounded with the mouflon of Europe. Perhaps they are the same species, and the differences between them are merely climatal, and therefore we have not added the systematic names to the common ones by which they are known. The argali is found in all the mountainous parts of the temperate and the cold regions of Asia, to the eastward of the Caspian, and even in places so cold as Kamschatka, where it is highly esteemed both for its flesh and its fat.

South Down Sheep.

It is an animal rather less than the fallow-deer, but thicker and stouter in the body, and shorter in the legs. The male is considerably larger and stouter than the female. The head has a good deal of resemblance to that of the common sheep, but the ears are shorter. The horns of the male are not very unlike those of the ram, but they are larger and higher, more compressed, more triangular in their section, more divergent, and also more rough and furrowed. In very old animals they are of great strength and thickness, especially at their bases. The front side is flat or very slightly convex, but toward the point the convexity is greater, and it is very compressed. The interior side is grooved for nearly its whole length; and the external one is a little convex in the basal part, and a little concave toward the point.

The internal angle on the front side is the most prominent; and the external of the same is rounded, especially in the old ones. The cross furrows and ridges with which the horn is annulated are very irregular. The female, when full grown, has the horns more elevated and less divergent than the horned ewes of the common sheep. They are compressed, flat on their inner surfaces, and convex on their outer. They have the angle of the convex edge rounded, and that on the concave sharp; but toward the points they are flattened and turned outwards. Both on the males and the females, these horns begin to make their appearance when the animals are about three months old. They are then semi-oval in their section, and of a black colour. The tail of the argali is very short, and naked on the under side, the same as in the mouflon. In winter, the colour on the upper part is generally greyish yellow, with a line of brownish red down the back; the buttocks bright yellowish; and the under parts and insides of the legs white. In summer, the colour of the upper part is generally more inclining to red, but the yellow patch on the buttocks surrounding the tail remains of the same colour at all seasons. The hair is very short and smooth, resembling that of the deer, and has hardly anything of a woolly appearance. It is remarkable for the fleetness of its motions and the vigour of its leaps, and in many points of its character it bears no small resemblance to the deer; though in the more essential ones it is decidedly a sheep, yet certainly more removed from the common sheep of Europe than the mouflon. It is an exceedingly lively and active animal, and its flesh is as much esteemed in the countries which it inhabits as venison is with us.

WILD SHEEP OF AMERICA. This is often called the "rocky mountain sheep," under which name a figure of it will be found in the plate SHEEP, which figure will give the reader some notion of the general appearance of the animal. By some the goat of the rocky mountains has been confounded with this animal; and it has also been called an antelope, though it is neither the one nor the other, but truly and properly a goat. The characters of this species, or probably variety (for it really seems that, notwithstanding all the diversities of the genus *Ovis*, whether in the wild or the cultivated state, there is no well made out distinction more broad than that of variety), are very apparent, and at once prevent any possibility of confounding it either with the antelopes or the goats, though of course, as all sheep do, it approximates more closely to the latter of these than to the former. The body is remarkable for its thickness and roundness in proportion to its length; the legs are very long; the outline of the forehead, seen in profile, is nearly straight; and the muzzle is almost exactly that of the common sheep. The horns of the male are very thick and large; they advance in front of the eyes, and form nearly an entire turn of a spiral. They are flattened laterally like those of the domestic ram, and have similar transverse furrows and ridges. These furrows and ridges are very conspicuous on the basal half of the length of the horn, but much less so on the terminal half; and of the three lateral faces the front one is the largest. The horns of the female are much more slender than those of the male; they are compressed, nearly straight, and without furrows; there are, in some instances, plates or folds of skin under

the throat, especially in the male; the tail is very short in both sexes; the colour in summer is generally greyish fawn, with a reddish or yellowish line down the back, and a large patch of the same colour on the buttocks; and the under part, and the insides of the legs, are either russet, yellowish, or of a white sand colour; in winter the colour of the upper part is more reddish, and the throat and breast are more inclining to white; but the patch on the buttocks remains much the same at all seasons.

According to the American naturalists, these animals are found in little flocks, of about twenty or thirty in each, on the rocky mountains, and extending southward as far as California. Several naturalists have expressed their conviction that the mouflon of the south of Europe, the argali of Asia, and the wild sheep of America, are only climatal varieties of one great species, to which they have given the name of "mountain sheep;" but whether this is or is not positively the fact, we have no means of ascertaining. Probability is in favour of it, however, and the more so that, among the domesticated sheep, which we have every reason to believe are all originally of the same stock, whatever that stock may have been, there are differences of external appearance fully greater than any which are to be met with among the wild ones; and we believe that, in the whole genus, there are no differences but external ones. Some farther confusion and uncertainty is produced among these wild sheep by the conduct of the keepers of museums, who have filled these with horns and other scraps, not having any history, and which have, in consequence, been referred to places where they are not to be found. The great puzzle in the history of this genus, however, is the proneness which it has to break into varieties, not only in different countries, but in the same country, and even in the same flock. There are, however, other two species or varieties which are worthy of notice, though even they do not settle, or tend to settle, the question of common origin.

THE BEARDED WILD SHEEP (*O. tragalephus*). This is the wild sheep of the mountains of Atlas, in northern Africa, but whether it is native there, or merely the common sheep that had been left to wander into the mountains during one or another of the many disastrous changes to which that part of the world has been subjected, it is not easy for us to ascertain at the present day. This species has been known to European naturalists since the middle of the sixteenth century, at which time a specimen was brought from the mountains of northern Africa. It was an animal of considerable dimensions, hardly inferior to the red deer, standing three feet and a half at the shoulder, and measuring four feet and a half from the occiput to the tail; the head, from the top to the nostrils, was one foot three inches; the horns nearly thirteen inches in circumference at the base, and so close to each other as to approach within a single inch; their curvature backwards and downwards; the length rather more than two feet; the section triangular; the faces with cross ridges and furrows, and the colour black; the ears of small dimensions; the cheeks furnished with long hairs, which divide into two tufts of a beard on the under jaw; the neck short and thick; and the sides covered with hairs pendent as low as the knees; along the neck, and great part of the ridge of the back, there is an erect bristly mane, which is particularly high and

tufted on the shoulders of the animal; there are also tufts, or brushes of hair, on the knees, but no callosity as there is in the camel and in many of the antelopes; the covering of the body, which is of a rusty black colour, is hard and rough, resembling the hair of a stag more than the wool of the common sheep. Indeed, we believe that the fine wool of sheep is wholly the result of culture, and appears only upon those that are in a state of domestication; and we find so many varieties of it, arising from climate, pasture, and other causes, that it is really very difficult to say what change cannot be produced in the covering of animals of this genus, though the cause of the change is, in many instances, a matter beyond our philosophy. The legs of this animal are slender in proportion to their length; on the fore feet the exterior hoofs are considerably larger than the interior ones. The females are also said to be of larger size than the males, which, if true, is an anomaly not only in the ruminantia, but in the mammalia generally. The account of this species or variety, as from the mountains of Barbary, is by Caius, at so remote a time as 1561, and thus it is open to some suspicion.

That there are wild sheep in the mountains which skirt the valley of the Nile, and by inference in all the other hilly parts of northern Africa, is placed beyond a doubt by the testimony of M. Geoffroy Saint Hillaire, who obtained one that had been killed near the gates of Cairo, though not common in that part of the country. It answered pretty nearly to the characters that have been mentioned, and was at least a fifth larger in size than the mouflon of the south of Europe. In fact, it appears to be a sort of connecting link between the goats and the sheep; but its history is still too imperfect for enabling us to come to any distinct conclusions respecting it. It appears to have been discovered by different authors, as if it were two distinct species, some calling it the *ruffed* sheep, and others the *bearded* sheep; but its appearance at different ages and seasons has been too little observed for enabling us to come to any definite conclusion respecting it.

The history of sheep in the natural state is one which, though of much interest, is attended with many difficulties. That they inhabited most parts of Europe in the very early ages appears to be a point not admitting of much dispute; and the question arises, what has become of their bones? This is a question put, not only with regard to the bones of sheep, but to those of the greater part both of the mammalia and of birds, none of which are found in preservation, except in places where they have obviously been covered by a deposit of earthy matters. The only answer appears to be that, in wild nature, there are bone-destroyers adequate to the consumption of all the bones that may be left on the surface. The action of the atmosphere and the sun is the most powerful and most constant in its operation in the warmer climates; and then, in addition to this, there are many animals which gnaw bones. Of these the most remarkable are wolves and hyænas; though there are also some birds which, though they cannot of course gnaw bones, yet swallow and digest them. Now it will be found that where there are wild sheep or other wild ruminantia still to be met with, there are either wolves or hyænas, or both; and though the hyæna of the north belongs perhaps to a more remote period than the sheep (of which, however, we have no positive evidence), yet the wolf was certainly a

contemporary of the sheep in every part of Europe in which wild sheep ever existed; and it is not a little curious that, in most places, the two appear to have become extinct in some localities at the same time. Many of the old accounts mention that wild sheep existed on the Scottish hills at an early period of the history of that country. Hector Boece, who wrote a history of Scotland in the early part of the sixteenth century, mentions that there were then, in the remote isle of St. Kilda, wild sheep larger than the biggest goat, with tails reaching to the ground, and horns larger than those of the ox. It is very doubtful whether this most eloquent but highly romantic writer can be implicitly trusted in any matter of history, and more especially of natural history; and, therefore, if the matter rested upon his authority only, we should doubt, or even deny, the existence of these long-tailed sheep in any part of Scotland, and, even with the corroboration of the bas relief found near Glasgow in the ruins of the Roman wall, we must deny the existence of those sheep in the island of St. Kilda. At the same time we are ready to admit that there have been breeds of tame sheep in some of the remote isles appended to Scotland, as, for instance, the Shetland Isles, the origin of which it is no easy matter to trace. In fact, the whole history of the sheep as members of the animal kingdom in the wild state, is a subject of the greatest uncertainty, and one upon which conjecture may be exercised without almost any limit. This is the more to be regretted as the animals, when in a state of domestication, or rather semi-domestication—for that is all which, in general, is arrived at in the case of sheep—are so very useful and so very abundant to the hand of the cultivator.

We shall say a few words on the varieties of cultivated sheep by-and-by; but we may mention, as part of the general account of them, that they appear calculated for performing a service in the cultivation of the earth which cannot be performed by any other domesticated animals. Sheep nip or nibble the herbage, and thus never pull the roots out of the ground. But they nibble it very close, and thus none of the grasses upon a sheep-walk ever come into flower. Now it is the habit of all the grasses, and perhaps of the kindly and succulent grasses more than any others, to "tiller" at the roots, and spread upon the ground, if the flowering is completely prevented. We believe that this is true not only of those grasses which are perennial, but of the annual grasses, and even of the cereal ones, which are in use as the bread-corn of all civilised nations. In as far as the last are concerned, it is, however, a matter of minor importance, because there would probably be but little profit in breeding them back to the wild state, in which they should be valuable only as pasture grasses. But, in the case of those members of the grass tribe which are of little or no use to man as food, the management so as that they form a carpet or covering to the surface of the ground is of far more importance. Now we have, in many parts of the British islands, very convincing instances of the advantages that have resulted from the pasturage of sheep. We do not allude to the value of the animals themselves, in their wool, their flesh, and their skins, though these have enriched many a man, and many a district; we allude to the advantage which the soil itself derives from sheep, and the tendency which sheep-pasturing has to bring land into a state fit for

tillage, or any other sort of culture. Those who have been for some time acquainted with those parts of the Highlands of Scotland, where the climate is not of so wet and dripping a character as to be injurious to sheep, do not need to be told how much the pasture improves under these useful and interesting creatures. It is true that in some places, where the sides of the hills are particularly bare and steep, the sheep tracks have cut the surface to such an extent that it has "peeled off" by the heavy rains, and left nothing but the bare gravel or rock, both of which are equally unfit for vegetation of any useful kind, or indeed of any kind at all; but situations in which this can happen are by no means fit for sheep pasture, not only on account of their steepness, but on account of their humidity, that is, of the habitual rainy character of their atmosphere.

In places which are sufficiently dry for being wholesome for sheep, these animals are the means of very great as well as of very speedy amelioration; and while, in those parts which are not pastured by sheep, heath, moss, and lichen consume the little grass that there is, and gradually convert the surface into one of the most sterile and hopeless character, in those which are pastured by sheep the grass extends, and the less valuable plants diminish. This effect is visible on very many parts of the Scottish hills, where sheep have been introduced for some time; and there is not a doubt that, after this kind of stock has been upon the ground for a considerable number of years, the soil may be, at very small expense, brought into use as tillage land; and the food of thousands may be obtained where but for the sheep there would not have been the means of supporting even one human being. Any one who chooses to inspect those parts of the Highlands of Scotland that have been for some time pastured by sheep will be able to certify what has been here stated, as to the effect of that kind of stock in ameliorating the condition of the ground. Wherever they have been, the heath, moss, and lichen are wearing away, and grass is gradually coming in their stead. The advantages which result from this are much greater than those who have not attentively studied such subjects would be apt to imagine. The heaths, mosses, and lichens produce bad mould—mould which is unfit for the production of any kindly plant; and their constant tendency is to cover the surface with hog-mould, which, when it once gets complete possession, is the ruin of everything else, and actually cuts up the better soil previously formed by the other plants, which it displaces. Any one who has examined, with even moderate attention, one of the numerous deep peat bogs which occur in the Highlands, and generally in all the cold uplands of the northern parts of Britain, must have been struck with the vast quantity of the remains of forest trees of large size—oaks, pines, birches, alders, and others, the greater number of which, the oaks especially, will not grow but upon rich soils; and yet, when the whole is examined down to the clay or sand which forms the bottom in such places, there is not one particle of the soil in which an oak, or any other of these trees, could grow, to be found. The top is spongy, and the bottom more solid; but there is not in the whole a single particle of earth in which any kindly vegetable could be grown. Yet, from what we know of the habits of the trees which are found in those deposits, there must once have been an abundance of rich soil; and

that soil has not been washed away by rains, or removed by any other mechanical means, for all is obviously in a state of nature, and the situations are places of deposit, not of wearing or wasting away. The question then arises, what has become of the rich soil that nourished those great oaks, and some of them are truly gigantic, which are now found buried in the bogs? The only answer that can be given to this question is, that the bog plants have not only exterminated all the more kindly vegetation on the surface, but have consumed the very soil by which those plants were supported, have destroyed both the produce and the land.

Now, if, in the places of its greater accumulation, this "poison of the bog," for so we may term it, is capable of eating up the soil which had sufficed for the growth of oaks of the largest dimensions, it follows, by obvious consequence, that, upon the general surface, where there is a cold and dripping atmosphere, the same plague will be able effectually to destroy the grasses, and all those more kindly plants which are available for the pasturage of stock. Nor is there any doubt that this is the cause which has rendered so much of the hilly parts of the country comparatively barren and useless; and pasturing with sheep appears to be the only means by which this evil can be cured. Therefore, these animals have a value beyond that which they yield in their carcasses and fleeces, great though that is.

This "poison of the bog," to which sheep appear to be the only certain and effectual antidote, is by no means a passive evil. When once established, it spreads, and no ordinary labour of man can arrest its progress. It invades the surrounding land, and invades it not merely with its presence, but with the climate which it brings along with it. That climate is decidedly a winter or polar one, one of cold and damp, and uncongeniality to every thing useful that the earth can produce. Summer is, in all temperate climates, really the winter of the mosses, unless they have so far got the better of every other kind of vegetation, as to have their own dripping atmosphere all the year round; and whenever this is the case, farewell to all that is beautiful or valuable on the surface of the earth. In average situations, the mosses are green and thriving only in the winter months; and whenever the state of things becomes such that they are green in the summer, then the almost necessary accompaniment is, that no other class of plants can be green at any season. In moss-clad places the winters are always extremely cold, because the mosses retain so much moisture, that every sunbeam in the latter part of the year is absorbed in the evaporating of it; and then, when the summer occurs, they are as liable to be parched with burning drought. They are constantly dying at the roots and growing at the summits, so that they very soon cover the earth with a deposit of moss in which no other deposit will grow; and thus the surface is ruined in as far as any valuable crop, or use in the finding of food for human beings, is concerned, once, and for ever, unless reclaimed at an expense of drainage and other means, which amounts to fully more than the fee-simple of the land. But this is not all; the evil, once having got the mastery in one place, steals onward in all directions; mildews and white frosts invade the portions under cultivation; and they spread and spread, till the whole country becomes barren and unprofitable. The writer of this article remembers well that

there was no ripening of corn in the vicinity of the peat moss; and that though peat earth, when not too much soured by tannin, which it always is if the bog contains many remains of trees other than pines, is not unfavourable to the growth of the potato, the leaves of these plants used to be blackened in the early spring, and the crop became a perfect failure. Where matters have proceeded to this length, no pasture of sheep can be of any avail; but it is only in particular situations where this can take place, and over the general surface of even a moist country which is hilly, the moss itself cannot accumulate, but in time gives way to lichen, and that absolutely eats up the heather, and the result is a surface of absolute sterility. If sheep are introduced in time, this may be averted, and the grass nibbled by them, and kept from flowering, may spread, and in time produce a more kindly and valuable surface, to which the droppings of the sheep contribute not a little.

There is another state of things in which sheep are not less valuable, and that is where the tendency is not to produce moss and peat-bog, but arid waste. This is the ultimate tendency of nature on the dry downs in the south of England; and it is still more marked and conspicuous in countries which are of a more dry and sandy character. Whether the pasturage of sheep could have prevented the formation of the Great Desert which extends from the west of Africa to almost the extreme north-east of Asia, is a point which cannot now be determined, because that desert is confirmed in its desolation beyond any thing that human ingenuity and power can accomplish. But there are many other regions in which things have not gone to such extremities, where the introduction of sheep has been attended with the happiest effects. Spain, Saxony, and Poland are remarkable instances of this. Estremadura, the province of Spain which borders upon Portugal from the Tagus southward, is a country of a very dry and sterile character; and, as will be more particularly noticed afterwards, that is the principal "run" for the Merino sheep, whose wool has been so long and so justly celebrated for the fineness of its staple. The breeding of fine-woolled sheep in Saxony is a later improvement; but it is one which has been eminently successful in those sandy places which had well nigh ceased to be productive in any other way. In Poland the advantages of the introduction of these sheep have been still more remarkable. That country was long famed for the production of corn; and those portions of it which are annually flooded by the great rivers are still fertile. But their fertility is kept up at the expense of the rest of the country. Great part of Poland consists of very thin soil over a substratum of sand and gravel. The rains are very heavy upon it in the autumn, and the summer is very long. The soil is thus apt to be washed off the heights; and though there is a deposit on the plains by the banks of the rivers, the whole country suffers an unusual deterioration. This has been very much increased in consequence of the drain of the country by armies, which has reduced the number of domestic animals far below what is required for an agricultural country. So much was this the case about the time of the close of the war, that hardly any of the land could bear to pay rent, and not much of it could be cultivated to any advantage. The annexation of great part of Saxony to the kingdom of Prussia, had the effect of causing many of the Saxons

to sell their lands and migrate to Poland, where they have carried on, upon a very large scale, the same sort of sheep farming which had previously been so successful in Saxony, and by this means the country is in a state of improvement equally certain and rapid. Places which, not long ago were plantless, or covered with the most noxious and unprofitable weeds, have come into grass under the pasturage of the sheep; and if changed circumstances should again render it desirable that the breadth of Poland should be a corn country, the pasturage of the sheep is preparing it for being so, and at the same time the present profit to the occupiers is far greater and more easily brought to market than the produce they would have obtained by any other means. Soil which is best adapted for sheep pasture is also well adapted for the culture of turnips and potatoes; and the introduction of the latter especially has been of vast advantage to all the dry and sandy countries southward of the Baltic. Where the land is favourable to their growth, potatoes yield more food from one acre of land than rye, which was the staple domestic bread of the people of these countries, yields from ten acres; and thus there is a greater supply of vegetable food along with the sheep-walk, and the mutton remains for consumption in the country, which is a luxury that comparatively few under the old system could command. We have felt it necessary to make these few observations on the national advantages that result from the cultivation of sheep, because the subject is in itself highly important; and because in many parts of our country, the love of practices merely because they are old, however bad they are, has caused a prejudice against it. No doubt the throwing of large tracts of hill-country into sheep-walk, has rendered it necessary to remove the cottagers, whose dwellings at one time spotted the wilderness. But, how much soever the tenants of these miserable abodes might be devoted to the ground upon which they were born, and how dear soever the customs of their fathers may have been to them, in the judgment of reason they were out of place for the general advantage of the country, and still more for their own personal advantage. No matter what the prejudice is by which the general good is retarded, for it is equally worthy of removal be what it may; and though the removing of it may in many cases require no small degree of delicacy, yet that should not prevent it from being undertaken. We shall probably have occasion to advert to one or two circumstances which show the value of sheep, when we come to speak of the several breeds, which we shall do in as few words as possible.

DOMESTIC SHEEP (*O. aries*). Whether the many varieties of domesticated sheep which are found in various countries, or in the same country, are descended from the wild runs now found in the hills, or from a race which has now become extinct, is a question which cannot be solved, neither would the solution of it be of very much importance. It is probable that there have been originally two races, one with the tails long and the other with them short; but neither this, nor indeed any thing to which we can at present refer in wild nature, can determine the question of origin. The variations which climate and culture seem to have produced on sheep appear in different parts of their bodies. In some the horns are diminished, in others they are increased, and even multiplied in number. In some again the coarse hair

which forms what may be called the outer clothing, wholly disappears, and leaves the whole body with only a soft and woolly fleece; while in others the coarse hair remains in greater or smaller quantity along with the wool. It does not appear, however, that the loss or the retention of the coarse hair has any very great effect upon the staple of the wool; for some of the finest woolled sheep, as for instance the old Shetland breed, have coarse hair and very soft wool under it. It seems a tolerably well-established law, however, that in humid climates sheep have a tendency to produce the rough hairs; that the wool is long in cold and exposed climates, where the sheep have to range much in search of their food, while on low and rich pastures the wool is much shorter. The form of the head, the size of the tail and various other characters, are altered by differences of breed and of pasture; but the causes of these are all very imperfectly made out.

There is one circumstance connected with this topic which it is important to attend to, and that is, the quality of the flesh, as connected with the character of the pasture. Sheep grow to a much larger size, and accumulate much more fat, upon rich pastures, where they have comparatively little labour. But this, though, in so far as quantity is concerned, the profitable state of the animal, is by no means the healthy and profitable one; and it is doubtful whether it is, on the whole, the most economical. As provisions of all kinds are valued and sold by weight, it is the interest of the grower to obtain, in all cases, as great a weight as possible; and, in order to obtain this, there is often a very great sacrifice of the quality. Quality, especially in such an article as mutton, if it be brought to market in a wholesome state, is very much a matter of taste, or, in other words, it is one which cannot be decided arithmetically, as pounds and ounces can be decided; and for this reason it is apt to be overlooked, or, at all events, to meet with less attention than it really deserves. From the superior flavour of wild animals above those which are tame, except in those cases where the flavour of the wild ones is too high, we may infer, that the nearer the condition in domestication is to that which it inhabits in free nature, the better must be the quality of the flesh. This is well established in the case of the sheep of our own country, where the mutton from the hills of Wales and Scotland, and also of the dry downs in the south of England, is vastly superior in flavour, more digestible and wholesome, than that of the large sheep of the low-lying pastures and midland counties. These are, therefore, clearly the places in which sheep ought to be bred with a view to their perfection as an article of human food.

Ought we, then, to abandon the flocks which look so well, and are so productive, in the rich and dry meadows? Assuredly not. But it is equally true that the flavour of the flesh cannot be retained if the sheep are bred "in and in," for a long time, upon these rich pastures. To breed in the uplands, and fatten on the plains, is a good rule in the case both of sheep and of cattle. Nor does it appear to be necessary that the animal should continue for a very long time on the upland. The quality, both of animal and vegetable substances, is determined from the beginning, or, at least, at a very early stage of existence; and, if it is transferred from the one pasture to the other while young, the quality of the upland, and

the quantity of the plain, may be both obtained in the maximum of perfection which they can jointly have in the same subject. These, however, are professional matters, though at the same time matters of great public interest; and we merely mention them to show how wide a field is opened up for useful study in the single genus, and probably species, of the sheep. We shall now enumerate some of the varieties or breeds, and in respect of these Africa appears to claim the preference over the other quarters of the world. The drought of the climate might perhaps lead us to expect this.

THE LONG-LEGGED SHEEP is one of the chief in the northern and central parts of Africa. The general characters are: the legs long, and the form of the body stout, but the flank not so plump as those of the European breeds: the profile of the forehead is arched; the ears stick out nearly at right angles to the central line; the neck is short; but the tail is proportionally longer than in the common sheep: there are two kinds of covering on the body; on the fore part it is long and shaggy, and on the hind part it is woolly; on the breast especially it is very long, and pendent almost to the knees; the horns are rather short, curving round the ears, but forming only a portion of a circle. This seems to be pretty nearly allied to the bearded wild sheep of Africa, of which mention has already been made. But there are breeds in the different parts of the country which vary a good deal in their individual characters, as one might be prepared to expect in so wide a country as Africa.

THE MOROCCO SHEEP have the rough hair on the fore part of the body shorter than in the general type of the race; but the wool on the other part is longer. The ears are small, and so are the horns, which curve outwards. The colour is in general white, but occasionally varied with reddish-brown or liver colour. They are pastured in large flocks on the dry plains, both between the mountains and the sea, and on the other side of the mountains toward the desert.

THE GUINEA SHEEP are without the long hair on the fore part of the body, and the long wool on the hind; and in some instances they are nearly without wool. The horns form nearly semicircles, with the points directed to the front. They are not long, but rather stout. The general colour of the Guinea sheep is white; but they have usually some black on the head; and it is said that, in proportion as the black is more abundant, the horns are smaller. The ears are pendulous in some of the varieties, and there are traces of goitres or enlargements on the sides of the neck. This breed is found not only in Guinea, but in the larger tracts of habitable ground which spot the desert. Some of them are without wool upon the body, and with a mane of silky hairs down the ridge of the neck, and partially on the shoulders. The females are without horns.

THE CONGO SHEEP, inhabiting as they do a climate almost immediately under the equator, and intensely hot, are almost wholly denuded of wool, or indeed of covering of any kind; and they are lank, and apparently feeble, as compared with the sheep of temperate countries. The hair upon them is thin and bare, and only a very little longer on the throat than on the rest of the body. The horns are very short, and bent backwards; the ears hang down the sides of the face; and there are two goitres or pendulous sub-

stances under the throat. The tail is long, but slender, and almost without hair; the flanks fall in very much; and the colour is white, with clouds and patches of dull rusty brown.

Of **ANGOLA SHEEP** there are several breeds, and they differ in many particulars from the last mentioned, as well as from each other. One of the most characteristic of these is the goitred sheep, which, in its external appearance, differs very much from the sheep which we are accustomed to see in Europe. They are lower on the legs than most of the breeds in the west of Africa. The hair upon the body is short and close, not in the least like the wool of common sheep. The ears hang quite down by the cheeks; the horns are very small, curving forwards; the outline of the forehead is very convex, and it is also rounded from the depression between the eyes to the muzzle. There are two appendages which tend to increase the irregularity of form in the head of this sheep. There is one large rounded accumulation, or rather two lobes of it, under the chin, and another, and rather larger one, beginning at the base of the horns, and reaching backwards a little on the occiput. These look as if they were deformities resulting from disease, but such is not the case. They are not glandular affections, like the goitres. They are provisions of nature for the subsistence of the animal at those times when, from the burning up of the vegetation in the dry season, it can find but little food. They consist of hard and curdy fat, very similar to what accumulates in the hump of the camel, or in the dewlap of the ox; and this sheep, as an animal something intermediate between the camel and the ox, has both the hump and the dewlap, only they are seated much farther forward on the body. Fat of this description is not so liable to be softened and turned to oil, by exposure to heat, as the common fat which animals accumulate in temperate climates; and thus it suits well with the habits of animals which inhabit tropical countries. It is only, or chiefly, in the gaminivorous animals that it is found; and it is found only in such of them as are not fitted for a very extended range of motion at the different seasons. The antelopes, for instance, are capable of dashing over many hundreds of miles; and they can thus follow the season of fertility, as it changes from latitude to latitude. Sheep have not this extensive power of ranging; and thus, in proportion as the dry season upon their pastures tends to produce sterility, they accumulate stores of this curdy fat to support themselves under it, whereas the ranging antelopes require no such provision, and accordingly they have it not. The camel, though a strong and patient animal, is not a ranging one, and it is also provided with a store in the hump against the time of famine in its native localities. The means which animals thus have of storing up a portion of the produce of the time of plenty, to serve them when the reverse comes, are among the most extraordinary and at the same time the most instructive adaptations in the whole animal kingdom.

One other character of the goitred sheep of Angola is the great length of the tail. It is not thick, or in any way loaded with fat, but it nearly touches the ground. The colours of the animal are generally pale brown on the upper part, and white on the under.

There are other breeds of sheep in the same country with this one, which, in some particulars at least, have more resemblance to the sheep of Europe; and

they are covered with longer and very fine wool; but they all have the very long tails and the pendent ears which are so characteristic of this one.

In Southern Africa there are many breeds of sheep which have been introduced by the colonists, and farther multiplied by crossing. Besides all those which are really sheep, the sailors call the albatross the "Cape sheep," because, when on the water, the size and colour of these birds have some fancied resemblance to those of sheep. There is, however, one Cape sheep which deserves the name, as being a native of the Cape colony. This species is

THE HOTTENTOT SHEEP, or BROAD-TAILED SHEEP. These sheep get their common English appellation from the enlargement of the tail, which is not, however, in the organ itself, but in an accumulation of fat upon the sides. This fat is of the same curdy nature as that in the goitre and occipital lump of the Angola sheep, and it is of course intended by nature to answer a similar purpose; but it is not a little singular that of two varieties of sheep, both inhabiting the same quarter of the world, the one should accumulate this store of fat on the head, and the other on the tail. It is, of course, of no great importance upon what part of the body of the animal this store of fat is accumulated, as the absorption of it, when required, can as easily be made at one part as another; but still there must be a cause for this difference, just as there is for the fat of some animals being outward, that of others inward, and that of others still distributed through the body.

The broad-tailed sheep of the Cape may be considered as an eastern race, in opposition to the sheep of Guinea as western races. It is smaller than the common sheep, and rather a handsome animal. The females never have horns, and the males are not unfrequently without them. The tail is long, though not so long in proportion as in the sheep of the west of Africa, and it terminates in a thin point, which is slightly turned outwards. The accumulation of fat lies on the outer side, where it increases the thickness of the tail more than it does the breadth. Its covering is not so properly wool as short white hair, which is pretty uniform over the body; but a patch over the eyes, the tips of the ears, and some parts of the legs, tawny. As found in southern Africa, these sheep are very delicate animals; and when taken on board ships, they waste away if the weather is severe.

This appears to be the parent race of the sheep in a very extensive range of country, namely, from the Cape of Good Hope northward, through Africa, and so through Asia, to the extreme north-east of China and the borders of Silesia. It is natural to suppose that, in so extensive a range, there should be many climatal varieties; and as these meet with the sheep of other places on the confines, and all sheep appear to have fertile progeny, how much soever the breed may be crossed, it is natural to conclude that there should be many mixed varieties arising from this cause. Mention is made of some at the Cape which are of larger size than the Hottentot sheep, and which blend the characters of these with those of the sheep of Guinea. This has the head of a black colour; the horns are longer, and the fat on the tail forms two lateral lobes, which, like that on the other, have the under side of the lobes quite free from hair.

From the peculiar zone of the earth over which it extends, and which includes nearly the largest line that can be drawn wholly upon land, these must

have, in the course of time, been the sheep of many races of men, and have been subjected to many changes in the altering states of their country; for there is no doubt that, within the period of human history, many thousands of miles of that country have passed through every gradation from the most fertile to the most irreclaimable desert. There is, of course, nothing in the present character of the sheep which can throw, or tend to throw, the smallest light upon the history of the countries; but, at the same time, they are not a bad artificial memory of the facts, if the history is once known. In the north-east of Africa there is a variety of the broad-tailed sheep which deserve the name more than that of the Cape, for the tail is so wide at the basal part that it extends completely over the buttocks. It has the line of the forehead nearly straight, the horns not unlike those of the *Argoli*, the wool very coarse, and the coloured parts of a deeper shade than in the Cape sheep, though they are marked in nearly the same manner. Another variety, found in northern Africa, and also in some of the rocky isles of the Mediterranean, has often more than two horns; their ears are slouched, the tail not enlarged, and the colour generally, but not in all cases, white. Several experiments which have been made show that, when the sheep of the warm countries, which are there covered with short hair, are brought into cold countries, they acquire the woolly coat of the ordinary sheep of those countries even at the beginning of the winter. They at the same time retain the agility in leaping which is characteristic of the sheep of the southern mountains, which are not encumbered either by a heavy fleece or by fat distributed over the body.

In Asia there are very many varieties of sheep, the greater part of them having more or less analogy to the broad-tailed race already mentioned. They are generally named after the countries in which they are found; and, as they often differ very little from each other, some confusion is produced by the same species or variety being obtained from different places, and called by different names.

One of the most celebrated of these breeds is that which is called the *Astrachan*, not of course from its inhabiting that city or even that province, but because Astrachan is the centre of the trade in the skins. Their furs are well known in all the countries of Europe in which furs are used; and vast numbers of them are sent to China by the caravans which traverse Siberia. These furs are called Siberian lamb-skins, Crimea furs, and other names. They are usually of a grey colour, produced by the mixture of black and white, and they are closely and very prettily curled. Some are quite black, and they fetch a very high price, though the fur can be dyed as other wools can; but then a dyed fur is a very inferior article both in appearance and in quality. The dye takes off the gloss of the fur, and at the same time weakens it very much, and loosens its adhesion to the skin. These furs are obtained at a great sacrifice of the value of the sheep, and also by the practice of what seems very revolting cruelty. They are the skins of the lambs taken from the uteri of the mothers just a few days before the time that they would be dropped in the ordinary course of nature. If the lamb is ever dropped, and left to dry in the atmosphere, the beautiful curl of the fur, in a great measure, goes off; and when the animal reaches its full size the character of the skin changes still more

by the white portion turning dull and yellowish, and long and coarse, so as to shade the fine grey wool which is below.

There is something revolting and also at variance with the sound principles of political economy in the obtaining of this fur. To sacrifice one animal for the sake of its skin is bad enough—only that it happens that the greater part of the fur animals are those which man makes a merit of killing, besides the value of the skin, as they are all predatory animals, and most of them very destructive ones; but the idea of sacrificing a ewe and a lamb for the sake of a lamb-skin, is one at which not only feeling, but frugality itself, stands aghast. Both the mother and the young are at this time unfit for human food, or, at all events, they are unwholesome and not nutritious; and the very sheep themselves read us a pretty sharp homily against this species of cruelty, for the sheep do not eat the flower stalk of the grass from the time that the flower appears till that at which the seeds ripen. In most cases there is a conservation by Nature itself in the time of reproduction, whatever may be the case with the young when they have separated from the parent, whether in the state of the organised animal or in that of the egg. It is perhaps a palliation of this cruel practice that it is performed by a barbarous people, and in a place where sheep are not of the greatest value; but still it is equally repulsive to the feelings of civilised men, and contrary to their notions of proper economy in the management of animals.

When full-grown the Astrachan sheep are below the ordinary size of the sheep of Europe. The horns of the males curve backwards, and are spiral toward the points; the ears droop very much; the usual colour is dull white in the upper and coarser wool, and grey in the under and finer; the tail is not very broad, but still it indicates that this breed belongs to the broad-tailed races.

There are many breeds of sheep in the south-east of European Russia and the adjoining portion of Asia, which differ from the sheep that yield the fur in the way that has been described, but all of which show that they are, to some extent or other, related to the broad-tailed sheep which, as we have already mentioned, occupy so vast a length of country from south to north-east. One of these is wholly without horns, has the line of the forehead nearly straight; the ears directed obliquely downward to the front; and appendages to the throat. It is white in the body, and the wool is of good quality; the face is of a dull yellow colour; and the tail, though very broad and overlapping the buttocks, is short compared with that of most of those connected with the broad-tailed race.

A little farther north in Siberia, and also in European Russia, there is another breed which, instead of being hornless like the last-mentioned one, has generally four horns in the male. These horns vary in number; they are rarely fewer than four in the rams, sometimes they are five, and in those cases one of them takes a central position, and in other cases they are six; they have appendages under the throat; and their covering, though long and thick, is very coarse, and may be considered hair rather than wool. They are very hardy animals, and endure without injury the severest cold of those parts of Siberia and eastern Russia in which they are found. Their covering is of mixed colours, generally reddish-brown and dull

white in the males, and dusky black and white in the females.

To enumerate all the Asiatic breeds of sheep would, however, be a very tedious and not a very interesting process; for what with differences of climate and pasture, what with the crossing of different races, the varieties are very many; and not only this, but, as is the case with many of the sheep of our own country, the same breed is often apt to break into varieties, the causes of which cannot be very easily explained, nor would it, in all probability be of very much value though we could explain it.

The *fat-rumped sheep* of central Asia have the accumulation of fat differently placed on the body from any of those that we have yet noticed; but it is of the same consistency, and, of course, answers the same purpose in the economy of the animals. They have the line of the forehead a little arched; the muzzle slender; the ears narrow and drooping, and the horns small or wholly wanting. There are a good many varieties of them, some with appendages to the throat and some without, and they are called Persian sheep, Tartarian sheep, and other names, according to the places in which they are found. Their colours are mixed, generally reddish-brown and white in the male, and dusky black and white in the female; their wool is fine, and though, in the different countries in which they are, they vary a good deal, they may be regarded as, upon the whole, a valuable breed of sheep. In the Caucasus, especially in Circassia, there is a peculiar breed which have the tails so long as to trail upon the ground. They have spiral horns of no mean dimensions; have coarse but very strong wool, and are generally coloured, and often altogether black.

In India there are several breeds; but altogether India is not very favourable for sheep, either in respect of wool or of flesh, as the one part of the year is too warm and dry, and the rains are too heavy during the other part. Some of the Indian sheep may be said to be wholly without wool, and they are as bare and lanky as skeletons. But in the high grounds some of the breeds are better; some of these have the coat neatly curled into little screws, and of a pure white colour. There are a good many varieties both in India and in China, but they are every way inferior to the sheep of the more northerly countries. The wool is in general very coarse, and the flesh is inferior. Animal food is so little used, however, by the people of these countries, and especially by those of India, that the rearing of sheep for the butcher is a matter of very secondary importance. The superiority of the wool is proved by the fact, that the coarse woollens of British manufacture are among the most saleable goods that can be carried to the Chinese market; and although the common people of India wear little else than cotton, yet the finer woollens are in demand for great personages, state appearances, and the decoration of the temples and idols.

In Europe the breeds are so numerous that the details of them would furnish matter for a volume of considerable size. In fact, Europe may be considered as pre-eminently, above all other parts of the world, the region of sheep; and this partly because they have been more attended to than in the other quarters of the world, and partly because the pastures are both more perennial and clothed with more abundant and kindly grasses. No part of Europe is without its sheep; and in very many places they form

Persian

Guernsey

Many horned

Rocky mountain

a most essential part of the wealth of the people. The changes which have been effected by crossing and other means of artificial treatment in the sheep countries, are almost inconceivable, and the parent stocks appear to have come from different parts.

The many-horned sheep which have been already alluded to as inhabiting far to the northward in Siberia, appear to be the most northerly of the European ones. They are found in Sweden and Norway, in the Feroe Isles, and in Iceland. The breeds in most, if not in all of these places, are, however, very much mixed in consequence of the importation after inclement seasons, which are very fatal to sheep in those inhospitable countries, of supplies from other quarters. Those sheep of the extreme north of Europe are rarely if ever white, but rather of different shades of a rusty brown. They are rather a small race, but very hardy; and instances have been known of their existing for a considerable length of time buried up in the snow; and, even in Iceland, some of them are left to shift for themselves during the winter, at which season they are said to scrape up the snow for lichens, much in the same way as the rein-deer in Lapland. They are well adapted to the severity of the climate in the nature of their covering, which consists of three distinct kinds; the first is long coarse hair, which throws off the rain or the snow like a thatch; the next is a very closely matted, but rather coarse wool, which is the portion in common use by the people; and the third is close on the skin among the roots of the others, and exceedingly soft and delicate. It is of this kind of wool, though not from exactly the same breed of sheep, that the very fine stockings were made, for which Shetland was once so celebrated, but which appear to have fallen off in late years. The proper Iceland breed have the horns very irregular in number, amounting to three, four, or five, standing in different directions, but not forming screws like the horns of many other sheep. Their legs are slender, and their hoofs long and sharp, so as to be well adapted for keeping a footing either on the rocks or on the ice.

The *Cretan* sheep, though not confined to the island after which they are named, and on the mountains of which they are very abundant, are remarkable for the shape of the horns. Their horns are large, and with a very marked crest or edge on the front; at the basal part they form one complete turn of a spiral, and then they form three turns of a loose spiral toward the points, the one rising above the other, and then the tip nearly vertical. This peculiarity in the form of the horns belongs to the male only, for in the female they are much smaller, nearly straight, and divergent from the head. These sheep are about the same size as the common breeds, and rather handsomely formed. Their tails are long, and their ears small, and inclining downwards; their wool is coarse in the staple, and waved or slightly curled; the body is generally of a whitish colour, but the face and legs are dark, and sometimes nearly black.

It is probable that this breed is in some way connected with the long and coarse-woolled sheep of western Europe; and there is a race in the hilly boundaries of the lower valley of the Danube which have some resemblance to them, and which are called Wallachian sheep.

Among all the breeds in Europe, the *Merinos* have acquired the greatest celebrity. It was in Spain that they first obtained this, though, according to the

chroniclers, they are of English origin, being the progeny of a score of ewes and fine rams presented by Edward IV. to John, King of Aragon, about the middle of the fifteenth century. How they came by their fine wool in Spain has not been stated; but if they are of an English race, it appears that that race has either become extinct or degenerated; for, until a fresh importation, no English sheep of modern times had wool of nearly the same fineness of staple. At present it does not appear that the transfer of these sheep to a warmer climate tends to make their wool finer, but rather that this is the effect of their being changed to a colder one. The wool which is now imported into England from Saxony and Poland is said to be superior to that which was formerly obtained from Spain, and it certainly is of finer staple than the Spanish wool of the present time, though there is no doubt that the long troubles to which Spain has been subjected have injured that as well as every branch of the industry of that unfortunate nation.

Whether from Spain, or from any other country into which the breed has been introduced and preserved in a pure state, this wool is superior to every other for the manufacture of fine cloths. It is a short wool, much matted in the body of the fleece, and curled into little screws at the points. It is best adapted for being spun into soft yarns, and the cloth is thickened by fulling, so that a piece of fine cloth partakes of the nature of a woven fabric, and also of a felted one. Its shortness and pliability fit it better for felting than any other wool, and it is superior to every other for the ground-work of hats, which are lighter, stronger, more water-proof, and hold the beaver better than any other material.

The west of Spain was the great place for these sheep, some of the flocks of which ranged, in the course of the year, over great part of the length of the kingdom. These travelling flocks were called *Transhumantas*, or passers over the soil, as distinguished from the *Estantas*, or stationaries, which remained in the same district. They usually wintered pretty far to the south, in New Castile, Estremadura, and even in Andalusia, but when the grass came up on the pastures, farther to the north, which was in March or April, they took that course, moving northward, as the heat of the summer began to parch the more southerly plains, and proceeding as far as the Pyrenees. They then began to retrace their steps, so as again to reach the south before the winter.

The *Merino* is rather a handsome sheep. The horns of the male are large, formed with spirals with the tips curving forward and outward, and the females are without horns; the body is thick and round, and the head rather large, with the profile of the forehead but little convex; the cheeks and forehead being covered with wool, make the head appear larger than it is in reality; the colour of the wool is pure white, but, from its closeness and oily nature, the dust adheres to it much more than to coarser wools, and thus, upon most pastures, the external colour is brownish.

Merinos have been often introduced into Britain, and valuable crosses have been obtained between them and some of the native breeds, but they do not appear to be very well adapted for British pasturage in flocks of the pure blood. In many places the climate appears to be too humid for them, and, generally speaking, there is not range enough on the pastures. There are also other considerations

U U

which have to be taken into the account. Fine wool, as is the case with all fine products, cannot be obtained but at a considerable sacrifice. Though

Merino sheep.

pound for pound, the wool of these sheep is much more valuable than ordinary wool, yet the fleeces are very light, the animals delicate, and the flesh inferior to that of many of the others; so that, all things considered, Merino sheep are by no means the very best adapted for a highly advanced state of agriculture. They would need the best of the land, but they would not pay the rent that land fetches in Britain. They, in fact, have their proper locality where the country is in a sort of intermediate state between absolute neglect and high cultivation. Besides, in the rearing of sheep, though the wool is a very valuable consideration, the mutton is far more so in all the more rich and valuable districts especially; and, generally speaking, in a country like Britain, where the land, like all other means of wealth, is understood to be worked up to the maximum of profit that it can yield.

The management of sheep kept for the profit which they yield, the points of excellence which distinguish the different breeds, and the whole details of these most interesting and valuable animals as the property of man, and one of the means that contribute most largely to the wealth and comfort of society, belong to rural economy rather than to natural history, even in the popular view of it. But still there is something so pleasing about sheep to people of all conditions, from infancy to hoary age, and there is such a filling up of the different pictures of rural innocence and enjoyment, by the appearance of the flocks which we observe on the different pastures, each so well adapted to that on which we observe it, that even the short notice to which we are necessarily restricted, in a work of so many subjects as the *BRITISH CYCLOPEDIA*, we cannot allow ourselves to be altogether silent on the subject. No one who has seen the beautiful contrast of the green meadows and inclosures, with their snow-white sheep, in such counties as Northampton and Leicester, can have forgotten the soft luxury and repose which they indicate—no one who has caught the balmy breeze of the spring upon the open downs of Sussex, and seen the wide-spreading flocks nibbling the surface till it emulates the softest velvet—and no one who has seen the dusky-faced tenants of the hill standing sturdily to windward, and facing the storm, or the island sheep

upon the wave-beaten cliff, bristling the array of horns over the expanse of that ocean whose tempered and humid breezes maintain constant plenty on those wild and craggy places—no one who has contemplated all or any of these scenes, can have forborne to feel how tame such would be without its sheep. We shall therefore cast a very momentary glance on the leading breeds of *BRITISH SHEEP* and their adaptations.

The feeding-grounds for sheep in the island of Great Britain, taking it in the whole extent of its surface, and the utmost variety of its soil and climate, may be reduced to four. These four are, of course, merely averages, and the kinds of situation to which they apply approximate each other on the confines, but they will show the general principle of gradation that runs through the whole. The four situations are: First, the rich parks, inclosures, and meadows, which alternate with the ground under tillage, and could themselves be profitably turned to that purpose. Secondly, the downs, or dry and rather elevated commons, which have a much thinner soil than the first, and could not yield an adequate return under tillage unless some extraordinary circumstances caused an unnatural demand for their produce. Thirdly, the high and rugged mountains, on which cultivation could not be profitable under almost any circumstances that could be imagined. Patches of these are often much more rich than any that are to be met with on the dry downs and commons; but the surface is more irregular and difficult, and the sheep require to be of stronger build and more hardy constitution. Fourthly, the small islands and rugged peninsulæ, chiefly in and toward the northern and north-western seas. These are not subjected to such alternations of heat and cold as some of the others, but they require to be formed and fenced in such a manner as to endure much rain and sleet, which are among the severest trials to which sheep can be subjected. We shall find that the native, or, at all events, the oldest breed in these last places, is that which we have already noticed as occurring in the extreme north from Siberia to Iceland, and which was, in all probability, introduced into the remote isles by the early Norwegians when they were lords of the North Sea. The breeds of sheep adapted to these localities, or which would be moulded by them, if allowed to remain long enough in full exposure to the climate, have differences pretty strongly marked. If we take them according to their wool, and in the order in which we have enumerated the different pastures, they are—long-woolled sheep, short-woolled sheep, rough-woolled sheep, and mixed-woolled sheep.

The characters of the bodies are: the long-woolled ones large in the body, and generally high on the legs; but they cannot be fattened, or even kept in good healthy condition, except upon rich pastures. They are too heavy for the fatigue of the uplands, and of all sheep they are the most quiet and gentle in their dispositions, and the least prone to range about. The short-woolled sheep are more compact in the body, with shorter and cleaner legs; they are much more easily fattened than the others; their flesh is much superior in flavour to the long-woolled sheep, and they are much more active and ranging, so that they are by no means so well adapted for farm-sheep in the meadows and enclosures, as they are always attempting to break through the restraints; and, even if they do not succeed, the attempts irritate

their dispositions, and prevent them from fattening so well as they would do on their own pastures, if they had more full range. The rough-woolled sheep are of a still more robust and energetic character, and can be reared and kept to advantage only where there is a wide range for them. They are bold and daring animals as compared with the other sheep, and they defend themselves stoutly against foxes and other predatory animals. Their wool is long, thin, and coarse in the staple; and although their flesh, when in good condition, is finely flavoured, they are by no means profitable sheep, unless in places where none of better quality can be introduced. Their chief recommendation is their hardihood both against the weather and in ranging about; and Burns mentions two of their bad qualities—

"Muirland rams,
W! woo' like gaita, an' feet like trams."

In the north of England and the south of Scotland we believe that this breed has been almost entirely replaced by other and more valuable ones, but it was once common on the hills; and the Lothian proverb, "As bold as a *Lammermuir Lion*," is not wholly ironical, but alludes to the fierce looks and daring character of the hill-sheep on *Lammermuir* as compared with the more gentle ones which had been introduced on the low grounds. The mixed-woolled sheep are a very hardy, but a very diminutive race, and yet there is reason to believe that they could be greatly improved by rich pastures; and, from their power of bearing rain with comparatively little injury, they might probably be introduced with advantage in many places where more delicate sheep cannot be kept in health.

Repeated crossings have produced a great many varieties in all these kinds of sheep, so that they approximate each other, and every sheep farmer that has the requisite knowledge of his business can readily find the stock that is best adapted for his farm, whatever may be its character. Not a little has been done by amateurs and societies for the improvement and adaptation of the breeds of sheep; but there have been occasional evils arising from the same source, as there always are in cases where men follow the dictates of authority instead of the judgment of experience; and there are few cases more likely to be mischievous in this respect than those that relate to sheep, where a very slight difference in the soil and climate demands a difference in the kind of stock.

The leading named varieties of the long-woolled sheep adapted to the rich pastures are—the *Lincoln*, the *Tees-water*, and the *Dishley*; but, in addition to these, there are many others.

The *Lincoln* breed have no horns; their faces are white, their bones large, their legs rough and stout, their skin thick, and their wool very plentiful and long, varying from a foot to a foot and a half. Twelve pounds, which is more than that of any other sheep, is about the average weight of the fleece, and the length makes the wool in much request for those fabrics which are not felted, or have a nap on them, and also with the frame-knitters. These sheep are accordingly bred in a great measure for their wool. Their flesh is, however, of coarse fibre and inferior flavour, and the animals cannot be fattened except on the rich meadows near the sea,

which are wholly or partially irrigated at certain seasons of the year. *Lincolnshire* especially, *Romney marsh*, and the other pastures which resemble these, are the best places for this breed when wool is the object. In places which are more dry and less rich, the carcasses can be fattened for market a year earlier than in those richer districts; but still the fleeces, of which there are three in the one case and only two in the other, and the greater age and weight, make the pasturing of them on the rank ground by far the more valuable. There appear to be many breeds which have originally proceeded from the *Lincoln*, and among these, in all probability, we must include

The *Tees-water*. They are shorter and lighter in the fleece than the original *Lincoln*, but they are more handsome, and very much superior in the carcass; their legs are longer, but more clean made; their bodies are thicker, broader in the back, and heavier, and the flesh is finer both in grain and in flavour. They are much better mutton-sheep than the *Lincoln*, though inferior for wool, at least in so far as quantity and length of pile are concerned. The two together are examples of breeding two races out of the same stock, and breeding each of them with a separate object in view—the *Lincoln* for the wool, and the *Tees-water* for the carcass.

The *Dishley* breed, called also the *New Leicester* and the *midland sheep*, is, at least appears to be, a breed from the *Lincoln* through the *Tees-water*. The method of obtaining these improvements consists, of course, in repeated selection of those individuals that have the wished-for quality in the greatest perfection; and whether the wool, the fineness of the fibre, or the disposition to fatten, be the chief object aimed at, it may in time be obtained without any positive crossing. The bones, the skin or pelt, and the wool, appear to go together, and an increase of them is accompanied by coarseness of fibre and difficulty to fatten. The increase of the wool is chiefly in the length, but that of the bones and the skin is in strength and thickness; but the long wools appear to have more strength than the short, that is, they afford more lasting fabrics, though not so soft and warm. The *midland* breed are very handsome sheep; their heads are clean and neatly formed; they are broad on the backs, and the body is cylindrical and very compact; their horns are slender; they fatten easily, and the flesh is excellent, not so high in the flavour as that of some of the hill breeds, but more juicy; their fleeces, not being naturally so oily as those of the short-woolled sheep, do not harbour much dust upon ordinary pastures, and thus they appear beautifully white.

There is another variety of long-woolled sheep, called *Devonshire Nots*, which have some resemblance to the *midland* breed, but are inferior to them in several respects. Their wool is coarser, their bones larger, and, though they make well up at the sides, they are ridgy in the back. This is their general character upon the richer pastures, but they are different on those which are bleak and elevated. On *Ermoor* they are less by one-third, with the bones very small, and the flesh of good quality, but the shape of the body is not good; and, though these sheep answer well where the land is of no great value, they would not be profitable in the agricultural districts. There are several other varieties of long-woolled sheep, but those which have been

noticed are the most extended and best known to history.

Of the short-woolled sheep there are more varieties than of the long-woolled ones. They are all of too roaming a character for the arable lands, and they are too delicate for the mountains. They are extending over most parts of the country, however, though, in proportion as they are more northerly, their pasture must be less elevated and exposed.

The *South Downs* are probably entitled to take the lead among the short-woolled sheep. They have the wool very short and fine; they are without horns; they have the face and legs of a grey colour, are light in the fore quarter, and have the back a little too ridgy; the hind quarters are very full and well shaped; and, though the carcass is light as compared with that of the midland sheep, the flavour is superior. The downs upon which the best of these sheep are pastured are mostly chalk, covered with short and fine herbage; and the sheep, especially on the higher walks, have the finest air and plenty of exercise, and are in consequence very healthy. There is nothing which shows the healthiness of a sheep-walk, and the fact of the exercise which the sheep have in feeding, more than the quality of the fat, which is always tallowy, and inclining to be rancid, when the pasture is unhealthy, or the animals have not sufficient air and exercise; and when thus improperly assimilated, and therefore indigestible and unwholesome, the quantity may be much greater than when the quality is very superior. South Down mutton is much in request in London by those who are particular in the flavour, though the larger sheep of the midland breeds furnish joints of greater show. The fleece of the South Down sheep, though of fine texture, is light, averaging between two and three pounds.

Though, therefore, they must be considered as good wool-bearing sheep, in so far as quality goes, the quantity is inferior; and their real value rests upon their superiority as mutton-sheep. If we take both quality and quantity into the account, they have few equals in this respect. They have not the exquisite flavour of the "wee sheep o' the Heelands," no doubt; but they yield better, and their flesh is both very digestible and very nutritious. It owes much of this to the fine pure air of the Downs, as well as to the small and sweet grasses; and though the wild thyme and the mountain trefoil give a zest, we are not sure that they add any thing to the wholesomeness, though they do not subtract. An engraving of the South Down is given on page 665 of this article.

The *Herefordshire* breed are of small size, but excellent quality. They have the legs and the face white, and the wool advancing upon the cheeks toward the eyes, though not so far as in the merinos. They are handsome little sheep, furnishing mutton of the very best quality; and the staple of their wool is fine, though the fleeces do not average above two pounds each. These sheep are housed during the night, in cots erected for the purpose; and on this account they are sometimes called *cotting* sheep. They are also called the "Ryland" breed, from the fact that the lands, upon which they were first introduced in stock as herded flocks, being of so light and dry a nature as to be fit only for the growth of rye. The continued pasturing with these sheep has, however, tended greatly to improve the quality of the soil, and the land is now equal to the production of any kind of

crop that may be suited to the climate. Thus these sheep furnish a very striking proof of the certain advantage of the introduction of sheep upon arid light lands, when these are so weak or exhausted as to be unfit for any of the more valuable kinds of grain. In tillage husbandry there is no amelioration for such lands, but by the application of manure in large quantity. But the very same circumstances which occasion the exhaustion of the land, lessen the quantity of manure procurable in the vicinity; and even if the manure can be had, great part of it is wasted, because it does not bring a covering of continuous vegetation to protect the surface during the severe seasons. It is worthy of remark that the parts of Saxony and Poland, into which the Merino breed of sheep has been recently introduced with so much advantage, partake not a little of the same character which tradition gives to the land upon which the Hereford sheep have been introduced with so decided advantages. That is to say, they were "rye" lands before the sheep were placed upon them; and not only that, but they were so far exhausted that the crops of rye had become very light. Thus we see that when we get hold of a sound philosophical principle in the study of nature, it carries us much further than we would *a priori* conjecture, and it always carries us in safety.

The *Dorset* breed is one of the most esteemed of the short-woolled sheep. They generally have horns, white faces, tall and slender legs, and long and rather thin bodies, but they are heavier than the South Down or the Hereford; their flesh is finely flavoured, and the wool, which is heavier in the fleece by a fourth than the South Down, is at least equal to it in quality. There is one property of the Dorset sheep, and of the lands of other countries that are related to it, which gives it an additional value over some of the others. By proper management, lambs may be obtained at almost any season of the year; at least they can be brought to the London market at or before Christmas, at which time they fetch a high price, and amply repay the additional care and trouble that are necessary in the procuring of them. This breed are pretty widely ramified over the south of England between the Devons on the one hand and the South Downs on the other; and they extend northward in the sheep tracks, till they come to blend with the midland breed formerly noticed. They differ much, however, in the different parts of their range, as attention has been paid to their various qualities. In some places, the principal object has been the carcass, in others the wool, and in others again the adaptation to some particular kind of pasture; and these have produced so many diversities of appearance that it is not easy to give a general description.

The *Norfolk* breed, which are chiefly to be met with in the dry parts of Norfolk and Suffolk, are a very discursive and restless race, and require very extensive pastures. They have large bones, long and strong grey legs, a long and thin body, black faces, and long spiral horns. They are of much larger lineal dimensions than the Dorset breed, but the weight is not greater, and the fleece, which, however, is short and fine, is only about half as much. The activity of this breed makes them consume a great deal of food, and therefore they are not the most economical in their keep; but the countries, where they are chiefly cultivated, are favourable for turnips, and the sheep

are less injured by being driven to market than almost any other race of the genus.

The *Cheviot* breed cannot exactly be said to be either long woolled or short woolled; and they do not agree very well in character with any of those in the south or the midland parts of England. They are an intermediate sort between the sheep of the grassy downs and those of the mountains, where, although many of the grasses are rich and sweet, the patches in which they occur are separated by barren divisions. The pure *Cheviot* breed may be considered as more peculiarly the border sheep, as the border hills, both of Scotland and of England, are especially their head-quarters; but they have been distributed from these over the greater part of the sheep grounds in Scotland, which are not very much elevated, and also into the mountainous parts of the north of England, which are too much elevated for the advantageous introduction of the *Teesdale* breed. They have been much mixed with other races; and, in different places, they themselves have been bred with various degrees of skill and care; so that there are considerable local variations in what are called *Cheviot* sheep. When pure, they have the face and legs white, and the former quite bare of wool; and the jaws are long, and the head neatly formed. Their limbs are lightly and cleanly made. The body is long, but there is a want of breadth both in the breast and the dorsal portion, though the latter is not ridgy. The average weight is nearly the same as that of the *South Downs*, and so is the fleece, but the last is longer and not so fine in the staple. It appears that this breed have been mixed with others, both at the upland and the lower boundaries of their pastures. The cross with the mountain sheep has taken place at the first of these boundaries, and that with the *Lincoln*, or rather the *Tees-water*, at the second. The cross with the mountain sheep is known by dark patches upon the face and the legs, a lessening of the size, and a deterioration of the staple of the wool, although with rather an improvement in the flavour of the flesh. It is against this deterioration that the observation of Burns is directed, when he alludes to the coarse wool and clumsy legs of the mountain sheep in the passage that has been quoted. The cross with the *Leicester* breed produces a sheep of very great value for situations moderately upland, as the hardihood of the *Cheviot* is in a great measure retained, while the plump carcass, and the lengthened fleece, rather increased in fineness, are to a considerable extent communicated. As already mentioned, the *Cheviot* and its crosses have been with much advantage introduced upon the secondary heights, in the eastern and central parts of the Scotch Highlands; and now that a rapid communication with London, by means of fast-sailing and ample steam ships, is established with the Forth, the Tay, and the Dee, there is no doubt that an additional impulse will be given to the culture of sheep in that end of the island, where it certainly may be carried to double its present extent with great advantage to all parties. As the fleece of the *Cheviot* is a secondary consideration in this traffic, and as it is limited to pastures upon which grass predominates, and where the climate is not too humid, it may be that the facility which is thus afforded in bringing the carcass, or rather the live animal, to the southern market, may cause fresh attention to be paid to the old mountain breed, which has certainly been treated with a neglect which it does

not merit; and no small part of the cause of this appears to lie in the fact that the improvers of sheep in the north, instead of looking at the state of things as before their own eyes, where they could have made the experiments, and acquired the information for themselves, have been carried away by what has been done in the south, where the physical character of the country is very different; and by pursuing this course, which is unquestionably not the wisest one, they do mischief with the "best intentions," and, like other labourers in the same vocation, glory in the doing of it.

The *Black-faced* heath, or mountain, sheep appear to have been the original breed in all the hilly parts of the north of England and of Scotland, excepting the extreme north and the isles. They are still the prevailing sheep in a considerable range of the country, especially on the hills of the rainy tract, through part of Yorkshire, Westmoreland, Cumberland, and Scotland, till they meet with the northern sheep, which, hardy as the black-faced breed, are still better able to endure the extreme severity of climate. They are in fact an exceedingly valuable breed; and, notwithstanding the smallness of their carcasses and the coarseness of their wool, it is probable that the replacing of them by more delicate breeds, has not been very wisely undertaken in many of the more bleak parts of the country.

They are easily known from all others by their black faces and legs, and by the large size of the horns in the males, which appear of harder and firmer consistency than those of almost any other sheep. They are also bold and daring animals, and of hardy constitution, not liable to the foot rot, even in traversing the boggy parts of the *Grampians*. The writer of this article has, in the course of his rambles among those delightful mountains, often met with the remains of sheep which had stuck in the mire, or fallen over precipices, but he never heard of disease among the black-faced flocks, though he often has among the other breeds that have been introduced by way of improvement; and this has again and again led to regret that those who have the wish and the means of improving the districts in which they reside will avoid what is before their eyes every day, and ground their proceedings upon what is projected or done in countries which have no resemblance to theirs, and very often by mere compilers of books, who have no acquaintance with the subjects of which they profess to treat.

The wool upon these sheep is coarse and shaggy, and may be compared to hair rather than the fine wool of the southern parts of the country. But there is a point here which is worthy of being considered, although often left out of the consideration; and that is, the durability of the wool. Under ordinary circumstances, the durability should increase as the square of the fibre, upon the supposition that the substance is of the same kind. But the fact is that the durability of the wool is in proportion to the hardihood of the animal upon which it grows; and there are many living who can remember how long the old fabrics, made of the wool of the black-faced sheep, lasted, in comparison with those of the present day, even on the supposition that there was the same weight of material in each of them. Mechanical improvements may have rendered the modern fabric cheaper than the old ones; but we would ask, what advantage is gained by a reduction of half the price

in the article, if it lasts for only half the time? The answer to this question will readily suggest itself to any one; but there are probably very many who have not thought on the subject of the injury that has been done to the labouring people of this country, by the endeavours which have been made to adapt the materials of the necessaries of life, and more especially those of clothing, only to the wants and wishes of that portion of the community who are anxious that an article shall wear out as soon as possible, in order that they may follow the fashion in getting another. There is not the least doubt that much misery to the labouring classes in Britain has arisen from this cause, and in none more than in the substitution of fine and tender wools for the stronger ones that were formerly in use. The writer of this article well remembers a countryman, then above seventy years of age, who, from the time that he arrived at manhood, had appeared every Sunday at church in his father's wedding coat, which, after the long period that it had been in use, really looked more fresh than the fabrics used by the same class of persons at the present day. The fact is that the low priced woollen goods that are now manufactured are made of rubbish, not unfrequently of woollen rags, which, after they have lain till half rotted, are torn to pieces by an engine; and, by another engine and the help of glue or size, twisted into yarn, which, without the glue, would be little more tenacious than a rope of sand. It is true, that this rubbish is cheap in the numerical tale of the money paid for it; but in reality it is not worth the cost or even the labour of the leisure time necessary for making it up.

These are considerations eminently worthy the attention of the legislature, and would no doubt receive it, if it were possible to find legislators possessed of the requisite degree of knowledge, which, however, seems to be a matter that is utterly hopeless; for with all the parade of their committees, commissions, and reports, some tons of which latter go to the limbo of waste paper every year, the actual result appears to be that the more they inquire into any subject the less they understand it; and that the most certain and rapid means by which any one matter can be wholly blotted out from the book of knowledge, is by the report of a committee or commission, which gets thanks for costing an abused public so many thousands of pounds. Our business, however, is with sheep, not with senators, and there is some consolation in the feeling that the one case is of far more substantial importance to the country than the other.

We have spoken of the durable nature of the wool of the black-faced sheep, and we may add, that the flavour of their flesh is unrivalled; and that, if bred and fattened on a proper pasture, a haunch of real hill mutton is superior to that of any park deer in the world. We must except the red deer of the free hill, which are tempered by the high spring tide of the elements, and also the mountain roe, which is a luxury in the good old and honest sense of the term; but truly among all the breeds of sheep, however full in the body or however fat they may be, there is truly nothing that comes up to the old black-face of the mountains; and we honestly think that the re-establishment of it in all those upland districts for which it is well adapted, is a matter of great national importance.

On subjects of this kind, feeling ought to be, as much as possible, left out of the question; and yet it is difficult to abstain from some admiration of the

personal character of this animal. It can hardly be exhausted by fatigue; there is no severity of weather which it cannot bear; and there are many recorded instances of its subsisting for weeks buried up under the snow. The ram, although not a large animal, is a very bold and powerful one; and when two meet to settle an affair of gallantry, there is a splendour in the conflict to which there is not much superior in the whole wars of the animal kingdom. The run which they take is much longer than that taken by the males of most races of sheep; and if they come into collision at the full swing of their impetus, the result is generally fatal to one, and sometimes to both. The bulls in the uplands, where the cattle are left to acquire the hardihood of nature, are powerful animals, but they quail before the charge of a black-faced ram when he is fully excited. As for the fox, they hem him round if they can find him, and when he is fairly in the circle, with the horns threatening him on every side, two retreat backwards, and then, advancing at the signal stamp of the foot, beat him to a pancake at a single effort. When in the season of excitement, they are prone to run at everything that is unusual; and a ludicrous story of this is told of and by no less illustrious a personage than the highly gifted and truly noble-minded "Sandy Wilson," whose "American Ornithology" will be in the freshness of immortal youth when every other natural history of birds is forgotten. Any of our readers who are acquainted with that illustrious child of nature, whose expatriation and the neglect of Burns are of those leopard spots upon the discernment and liberality of Scotland, which must keep her long or for ever in the class of the low and ungrateful among nations, must be aware that he followed for a time the trade of a pedlar. While he was thus employed, some circumstance, we forget what, revived the story of the rich gold mines in Crawford moor, of the produce of which the broad Jacobuses are said to have been made; and many persons resorted to "Crawford Burn" in order to search the sand and gravel in its bed for a portion of the treasure. [We have generally found the reported gold-dust of many parts of Scotland to be nothing but gold-coloured mica, but *n'importe*.] Wilson went, among others, and leaving his pack on the high bank, descended, shovel in hand, to find his fortune in the pool below. A "muirland ram" espied the pack, as an intruder on the pasture of the flock of which he was the patriarch and the guardian, and advanced toward it upon a *reconnoissance*, on which he was very close in his examination. After he had finished his survey he retreated backwards, as is the custom with rams, till he had gained the necessary distance; and then collecting his energy for the charge, he rushed upon the pack, and sent it endlong into the pool, sousing Wilson with the spray produced by the splash. Wilson immediately got out the pack, and spread his muslins and lawns to dry in a place where they were secure from the ram; and while waiting the operation of the sun and air upon them, he composed a very choice poem on the inordinate passion for wealth, he himself being the subject.

We have mentioned this anecdote for various reasons: First, it is highly characteristic of the black-faced ram, as offering battle to whatever intrudes on the pasture of his flock; secondly, because every reader of natural history must love to hear the name of Wilson repeated as often as possible; and, thirdly, because no independent Scotchman should fail to

"twit" his inconsiderate and narrow-minded country with the loss of such a man as Wilson, who became great in the American wilderness, despite the utmost rudeness of nature and of man. There has been, of late years, no lack of great squires and small knights perambulating different parts of Scotland, for the avowed purpose of examining nature there, and returning and getting laudation from coteries of aged persons for having discovered—nothing, and blessing their own wits upon the occasion, because the burthen thereof had not weighed them down, and made the maw of the hooded crow their monument. But if Scotland had had Alexander Wilson to perambulate the Highlands and Isles, and tell the tale of nature there, then Scotland would have been rich in one volume of her own natural history; but Wilson flourished and died in exile, and thus far forth Scotland is, and must remain—a beggar. Such at least is the opinion of the author of this article.

There is much more that we could say on the subject of the mountain sheep, which we have contemplated so often and with so much pleasure in the very wildest of their haunts; but our measure of space is full to overflowing. We must, however, mention that there is no possibility of tracing the genuine black-faced sheep from any foreign race in Europe or in any other part of the world; and thus we must look upon them as the aboriginal sheep of the wild parts of the British islands, and perhaps as the only breed that can be regarded as native. For this reason, as well as for the other reasons that have been already hinted at, they will merit attention as to the means by which they could be improved, not by crossing and admixture with other breeds, but in themselves as a race. On some of the heights of Cumberland there is a race nearly allied to this; the origin of which is unknown. These sheep have shorter and finer wool than the common heath sheep, and their faces are brownish or bluish, or mottled with these colours rather than black; but they are a very hardy and valuable race for elevated pastures. They have been farmed out to the shepherds for a long time; and, as is said, it is on account of this that they are called Floodwick sheep.

In some of the eastern parts of the Grampians, especially on the hills of the county of Mearns, and part of Aberdeen, there is another race of dark-faced sheep, which appear to have been imported from the north of Germany or from Norway, and which differ in some respects from the mountain sheep which we have mentioned as probably being indigenous. These are, in some places at least, called "bronkie-faced" sheep, in distinction from the real mountaineers, which are called "morifaced" sheep. The last of these is expressive of the black colour, and the other implies that it is mixed or clouded like the colour of a badger. These mountain, or rather hill sheep, unquestionably of continental origin, though not to be confounded with the mountain breed, which are more decidedly from Norway, appear to have been introduced only into those parts of the uplands of the north, which were colonised from the east, and not by Celts. Their wool is finer than that of the black-faced sheep; and the fleeces are often of nearly the same colour as the faces of the sheep, the dark parts of which are brownish in some, and inclining to grey in others. When stockings, knitted upon hand-needles formed great part of the occupation of the females on that side of Scotland, the coloured wools of the

sheep under consideration were in much request; and they were very durable, and by no means unhandsome in the colour. The sheep now mentioned are sometimes termed the dun-faced breed; and they approach a little in character to those of the western and northern isles, though they are not exactly the same.

The native sheep of the western isles are a very small but very hardy race. They have the face and the legs white or brownish yellow, but the fleece varies much both in colour and in staple. Upon the richer and more grassy isles it is very soft and fine; but on the higher and exposed places where the pasture is poor, it is much coarser in the staple. The wool is in very small quantity; and the entire carcass does not weigh more than half as much as one hind-quarter of the midland sheep of England. In those parts it is only in particular situations that the sheep get fat; but there is either something very delicious in the flavour of their flesh, or the air of the isles is a most excellent sauce, for we never ate mutton with so much zest as we have done in the Hebrides, where, at the time to which we allude, an entire sheep, wool, skin, and all, could be purchased, even by a visiter, for four shillings, and in some places for three. These islands are eminently worthy the attention of lovers of nature; and those who resort to them for pleasure should catch their own fish, and buy their own mutton in the live carcass.

There is some uncertainty in the history of the Shetland sheep. The original breed were very small and remarkable for the extreme fineness of their wool; but in so remote a situation, and one which is so much at the mercy of the contingent winters of the North Sea, they are now rarely to be met with. The other breed in these islands which is understood to be a more recent importation, though whence is not very clearly ascertained, are thus described: "They have three different successions of wool yearly, two of which resemble long hair more than wool, and are termed by the country people *fors* and *scudda*. When the wool begins to loosen at the roots, which generally happens in the month of February, the hairs or *scudda* begin to spring up; and when the wool is carefully plucked off, the tough hairs continue fast until the new wool grows up about a quarter of an inch in length, then they gradually wear off; and when the new fleece has acquired about two months' growth, the rough hairs, termed *fors*, spring up and keep root, until the proper season for pulling it arrives, when it is plucked off along with the wool, and separated from it at dressing the fleece, by an operation called *forsing*. The *scudda* remains upon the skin of the animal, as if it were a thick coat, a fence against the inclemency of the seasons, which provident Nature has furnished for supplying the want of the fleece." So say the authorities; but we cannot say there is much regard to Nature, however provident it may be, in their tearing the wool off the living sheep, and patches of the skin along with it.

SHELL-FISH. The ordinary name given to various crustaceous animals, such as the lobster, crab, scaly lobster, prawn, &c.

SHEPHERDIA (Nuttal). A genus of North American deciduous trees bearing diœcious flowers, and belonging to the natural order *Elæagineæ*. This genus was called a *Hippophae* by Linnaeus. The species are propagated by suckers, layers, or by ripened cuttings under a hand-glass.

SHREW (*Sorex*). A genus of mammalia belonging to the insectivorous family of *Carnassiers*, or eaters of animal substances, in Cuvier's arrangement. They are small animals of obscure and retiring habits, and the number of the species, and the countries which they inhabit, are not very clearly ascertained. They are not, however, animals of very great importance; because, whatever may be their use in wild nature, they do very little good and no harm to man. In so far, however, as they have any bearing at all upon human economy, they must be set down as the benefactors of man, which is true of all the insectivorous mammalia, with the exception perhaps of those which plough up the ground—the mole, for instance; and, notwithstanding the disfigurement of the ground by moles, the fact of their being injurious on the whole is far from being fully established; for, as the mole is very voracious, and feeds in the earth, it is more than probable that the small animals upon which it lives would, but for it, do far more mischief than it does. The animals which the shrews most nearly resemble are those of the genus *Mygale*, called musk shrews, but still they have sufficient distinguishing characters.

In the case both of the genus alluded to and of the shrews, some naturalists have been puzzled as to the proper place they should hold in the system—that is, whether they ought to be classed with those members of the rodentia which they resemble both in their general form and in their habits, or with the insectivorous *Carnassiers*. It must be admitted, that the line of distinction between these is not always so clear, as that one not very much skilled in natural history can draw it—the more so, that the animals of both orders which thus approximate each other are equally prone to eat animal matter. The distinction is, however, founded upon a character which, when it is once known, is not easily mistaken or misunderstood. The true character of the flesh-eating animals is in the canine teeth, though the strength of the mouth is thrown differently upon them in the different races. The character of the *Rodentia*, again, is in the incisors, and, whatever the character of these may be, the rodent animal cuts as with pincers, instead of inflicting punctured wounds like those which are inflicted by the canines of the carnivora.

The teeth of the shrews are generally thirty in number, namely, twelve in the under jaw and eighteen in the upper; but they have sometimes two less in the upper, which, of course, reduces the total number to eight-and-twenty. In these teeth, however, the distinctions of the three kinds cannot always be very clearly made out. That three of the cheek-teeth in the back part of the jaw have the bristling tubercles or points which are characteristic of all the insectivorous *Carnassiers*, cannot be denied or overlooked; but it is not always easy or possible to assign their proper functions to the teeth in the anterior part of the jaws, so as to say decidedly which is incisor, which canine, and which cheek-teeth. The three tuberculous teeth, which are the only true cheek-teeth, have before them five, or four, false molars in the upper jaw; and in the fore part of each jaw there are two long and crooked teeth on each side, and those in the upper jaw have a second branch or tubercle at the base. The teeth of the shrews are thus very different in their forms from those of the true *Carnivora*, and yet they do not very much resemble those of the *Rodentia*, for these have the long teeth at the middle of the jaw and close to each other, whereas,

in the shrews, the long teeth are apart with short ones between them. The shrews are furnished with a muzzle somewhat produced, though shorter than that of the genus *Mygale*; and the form of the head is that of a truncated cone, of which this muzzle forms the vertex. The tongue is thick and conical, with furrows on the surface, and corresponding furrows on the palate; the organs of hearing are in general well developed; but most of the shrews can make themselves deaf when they please by means of membranes which shut up the auricular openings. In this double membrane of the external ear they have a considerable resemblance to the bats; the eyes are similar to those of the mole and other *Carnassiers* that live under ground; the optic nerve can hardly be traced, and there are hardly any traceable nerves except some branches of the fifth pair; the usual muscles for moving the eye are also hardly traceable; and the ball of the eye is little else than a mere point; in fact, it appears that the shrews have very little dependence upon this sense. This is one of the great points of distinction between them and the rodent animals with which they have sometimes been confounded. Another character of the shrews is the odoriferous glands which they possess. The odour given out by these has some resemblance to that of musk, but it is, generally speaking, offensive. The situation of those glands is different from that of most, or all, of the other mammalia that have them. In general they are situated far backwards, but in the shrews they are on the flanks, nearer the fore legs than the hind ones. There are some peculiarities in the structure of these glands, but they are of too technical a nature for popular description. Indeed, the animals in themselves have so little interest, that the notice of them is more a matter of curiosity than any thing else, and yet they are so peculiar, and have resemblance to so many races, that there is little doubt that if their very obscure manners could be brought to light, they have a very interesting tale to tell in the relation of the mammalia.

In their external appearance, and the colour and covering of their bodies, the shrews have a considerable resemblance to some of the smaller members of the rat family, and the popular name given to them in many parts of the country is "shrew mice," under which appellation the water shrew is not unfrequently confounded with the water mole; but a very little attention suffices for distinguishing the one from the other. The conical head, the produced snout, the apparent smallness of the cerebral cavity, and the imperfect formation of the eyes, at once point out the shrews. The mammae of the females also disappear, or at least can be found with difficulty, unless at those times when they are wanted.

In fact, we find in the shrews approximations to so many animals, and at the same time so many characters which are peculiarly and exclusively their own, that it is impossible not to regret the little that is known of them. In their eyes they have a very considerable resemblance to the moles; in their ears there is an affinity to the bats; and in the absorption of the mammae, and also in the near approach or absolute junction of the passages in the female, there is some resemblance to the *Monotremata*. They are also found in most parts of the world, with the exception of Australia, and they may be there; and, in all situations and climates, their habits, so far as they are known, are very much the same. They

have indeed two modes of life in different members of the genus, some living in dry places, and some by the banks of streams and pools, and the margins of fountains; but they all live in comparative concealment, and in the earth rather than on it. They generally live in holes, but some get into hay stacks and other collections of dry vegetables, which they render very unpleasant by the odour which they give out. Cats and dogs are prone enough to kill shrews, but neither the one nor the other will eat them, probably on account of their rank and disagreeable odour. As is the case with most animals that have something disagreeable about them, and are but little known, the shrews have been supposed to be poisonous, and the common one stands accused of inflicting serious diseases on domestic animals by its bite; but there is not the least truth in the accusation; and, unless in the case of the insects and larvæ on which they feed, and in the consumption of which they in all probability perform a very important service, the shrews are among the most harmless of the mammalia. Even when we leave out a number of other animals which have been called shrews, the species are rather numerous, and it is easy to make more than there are in reality, as some of them are subject to much variation in colours. We can afford room for a very short notice of the most remarkable only.

COMMON SHREW (*S. araneus*). This is found in almost all parts of Europe, but is rarely seen in proportion to its numbers. Its general colour is greyish-brown, more or less reddish on the upper part, and ash-coloured on the under, the colours melting gradually into each other on the flanks. Colour, however, is hardly a proper foundation for the description of it, as some are brown, some yellowish, and some white. It is, however, only the points of the hairs, generally speaking, that have these diversities of colour, excepting in the white ones, which are true albinos, and have the whole length white; for the greater part of the length of the hairs is generally bluish-grey over the whole body. Around the muzzle the colour is a little brighter than on the rest of the body, and a small portion of the tail is usually of a bright brown colour; the ears are naked, large, and rounded, and conspicuous through the fur on the head, though there, as well as on the body, it is long and close; the teeth are conspicuous, and of a pure white colour; the mustachioes are very long, and they are often continued from the angle of the gape to the occiput; the tail is nearly round, covered with short hair, and about an inch and a half in length, which is nearly one-third of the whole length of the animal. The young differ but little in appearance from the old. The common shrew is not rare in most parts of Europe. In the summer it is found in woods and copses, and under hedge rows; but in winter it often takes up its habitation in stables, farm-yards, and heaps of manure, in neither of which places it does good or harm, at least in so far as is known.

TUSCAN SHREW (*S. Etruscus*). This is the smallest of all the European species, and rather a handsome one in its appearance, at least in its colours. It is only about an inch and three quarters in length from the point of the muzzle to the origin of the tail, whereas the common one is about three inches in the same extent. Its colour is brownish on the upper part and greyish on the under, the fur being particularly bright and shining. It is usually

found lurking under the tangled roots of trees, or in the hollows of decayed ones, though it often burrows in dunghills during the winter, probably because it finds food more abundant there than in more cleanly places.

THE PRETTY SHREW (*S. pulchellus*) is an Asiatic species, described as being found on the sandy and half-desert tracts of the interior. It is one of the very smallest members of the genus, being less than the Tuscan which was last mentioned, and little more than an inch and a half in length in the head and body, and the tail is about three quarters of an inch; the flanks are of the most snowy whiteness; the top of the head is bright grey, which extends on the back in a deeper tint, and forms a parallelogram, bounded laterally and backwards by the pure white, in the middle of which parallelogram there is a single white spot; the ears slate-colour; the muzzle is long and very pointed. This prettily marked species inhabits the dry sandy districts, and has been observed both in central Asia and in the north of Germany.

THE MARKED SHREW (*S. personatus*) is an American species, about the same size as the common shrew, and not very different from it in colour. The breast and the under parts are ash-colour, and the feet are reddish; the hair on the head and the tail is very long, and on the former it completely conceals the ears; the head and body are about two inches long, and the tail is about one inch. There is another North American species, mentioned under the name of the small shrew, which resembles the present one in most particulars except colour and size, and, from what is remarked of the common shrew, these can hardly be admitted as specific distinctions. It is probable that, in a wild country like America, there are many species or varieties of shrews, but there is not much of interest in their individual histories.

THE SHORT-TAILED SHREW (*S. brevicaudatus*) is another American species or variety. It is dark lead-colour on the upper part, and the same colour, lighter in the tint, on the under; the teeth are thirty in number, of a brown colour in the greater part of their length, but with the crowns black; the feet are white, with the three middle toes of nearly the same length, and the two lateral ones much shorter; the tail is short, rather thickened in the middle of its length, and very soft and velvety in its covering. It is rather a large species, being about three inches and a half in length, with the tail only one inch.

THE SQUARE-TAILED SHREW (*S. tetragomerus*) is a European species, nearly of the same size as the common shrew, but distinguished from all the others by the form of the tail, which is four-cornered, or nearly square in the section, the angles of which are very conspicuous; there is a sort of furrow along the under side, and the organ terminates in a very fine point; the ears are much shorter than those of the common shrew, but they are not completely covered by the fur; the colour is blackish-brown on the upper part, and greyish-ash on the under. It has been most carefully noticed in France; but, as its habits and haunts are the same as those of the common shrew, it is probably only an accidental variety of that. Gardens and farm-yards are the places in which it is usually found.

THE FLAT-TAILED SHREW (*S. constrictus*) is another European species or variety, of nearly the same size and habits as the common shrew. The characters

are: thick fur on the sides of the muzzle, which make it appear shorter and thicker than it is in reality; the ears short, and completely hidden in the fur; the cranium is larger and more rounded than in the common shrew, but the difference of intelligence in the two has not been ascertained; the tail is straight, flat at its origin as if it were strangled, thick and rounded in the middle of its length, and flattened again at the terminal part, and the fur at the point forming a sort of brush; the fur is very long, and soft to the touch, black in the greater part of its length, and reddish at the points; that on the throat is ash-colour, and on the belly grey. It has been observed in several parts of Europe, and also in the United States of America; but it is probably nothing more than a variety of the common shrew.

THE WHITE-TOOTHED SHREW (*S. leucodon*) has been named from the colour of the teeth, which, contrary to what appears in most of the shrews, are white to the points. It has been noticed in the valley of the Rhine near Strasbourg, where shrews are either more numerous, or have been examined with more care, than in any other part of Europe. It is about the same size as the flat-tailed variety, but with the tail of the same form as that of the common shrew; it is brown on the back, and white on the under part; but little or nothing is known of its manners, and it is in all probability merely a variety of the common shrew. We have often, in the course of this work, had occasion to notice the close connexion that there is between the covering and the teeth of the mammalia; and when we find, in any race, a disposition to break into varieties in the one, we may expect to find the same in the others.

THE LINED SHREW (*S. lineatus*) is another species or variety which has been noticed in France. It is of a brownish-grey colour, inclining to ash on the under part of the body, and white on the throat; there are two white lines extending from the nostrils to the top of the forehead, which are the foundation of the name; and there is also a tuft of long white hairs in each of the ears. It has been met with in the neighbourhood of Paris, and in some other parts of France, but it is rare; and the peculiarities of its manners, if they differ in any thing from those of the common shrew, are not known.

THE OARED SHREW (*S. ramifer*) is another which has been noticed in France. It resembles the preceding one in some respects, but it is of larger size than the generality of the shrews, being four inches long in the head and body, and two and a half in the tail; the general colour of the fur on the upper part is blackish-brown, that of the under brownish-ash on the belly, and white on the throat, or pale ash-colour with a reddish tinge; there is sometimes a spot of reddish-white on each ear, sometimes only on one, and sometimes it is wanting altogether; the tail is the most peculiar part; it is quite square in the basal two-thirds of its length, with the upper and lateral faces perfectly flat, and the under one with a longitudinal groove or furrow; the remaining third of the tail has a keel or ridge, chiefly on the under side, which makes the tail have something the appearance of an oar, which is the cause of the name that has been bestowed upon the animal; the feet have also long and rather stiff hairs at the sides, which, together with the form of the tail, show that this animal is less or more aquatic in its habits. Like most of the others, however, its manners are but very little known.

THE WATER SHREW (*S. fodiens*), is the one which has been improperly confounded with the water mole. It has many characters in common with the last-mentioned, which is also a water shrew, but there are distinctions between them. This one is generally about three inches in length, with the tail about half as much. On the upper part it is blueish brown, and on the under with a trace of ash-colour or of reddish, and the colours are distinct at the line of their junction, and do not melt the one into the other, as in the oared shrew. The outsides of the legs and the rump are of the same colour as the back; the upper lip, and a little spot on the place of each eye, are whitish, and there are sometimes traces of spots on the ears. The paws are reddish but the toes are whitish, and the incisive teeth are reddish toward the points; the tail is not unlike that of the species immediately preceding in its general form, but there is a white line along the under face, and the hairs which make the tail a swimming organ, are in proportion more produced. It is found along with the oared one, on the margins of pools and streams, and there are some accounts of combats between it and the frogs. This species is pretty generally distributed in the living state, and mention is also made of its fossil remains.

THE SACRED SHREW (*S. religiosus*), is a species which has some fame, or at least name, in history, as it is understood to have been one of the animal gods of the ancient Egyptians. Mummies of more than one species have been found in the tombs at Thebes. That which is considered as the true sacred shrew is about the same size as the masked shrew of Europe, but with the tail larger, the ears larger, and the inner toe shorter. There is, however, nothing of interest about the animal, except in the eyes of antiquarians; and the Egyptians were so indiscriminate in their adoration of animals, that having been a god in their mythology is no great honour.

THE CREAM-COLOURED SHREW (*S. flavescens*) is one which is easily distinguished by the peculiar colour of the upper part, which is a very pleasing shade of reddish cream-yellow, which passes gradually into bright ash colour on the tail. The head and all the under surface and insides of the legs are pale ash. There is a conspicuous line of brown on the forehead. The ears are longer than in the common shrew, but not so broad in proportion. All the teeth are white for their whole length, and the claws on the toes are whitish. This is, among shrews, a large species as well as a handsome one. The body and head measure fully four inches and a half in length; but the tail is shorter than in the majority. This species is abundant in Southern Africa, for which reason it is sometimes called the Cape shrew, though this name has been given to another species, which appears to be a native of India, and not of the Cape country. Its manners are as little known as those of most of the others.

THE INDIAN SHREW (*S. Indicus*) is still larger than the cream-coloured; but if we know enough of shrews to be able to subdivide the genus, the two would fall within the same subdivision. This one is nearly six inches long in the head and body, and the tail is about an inch and a half. The tail is not flattened in any part of its length, which proves that it is a land shrew, and not an aquatic one. The general colour of the fur is greyish brown; but, on the upper part especially, the points of the hairs are reddish. There are, however, many species in the south and the east

which are but little known, and they appear to have been very much confounded with each other.

THE GREATER SHREW (*S. giganteus*) is one of these. It is about half a foot long, with the tail nearly half the length of the head and body. This species is common in many parts of India, where it lives in holes and other obscure places, reposing during the day, and coming abroad only in the night. It appears to have at one time been very generally distributed, if it is not so still; for it is one of those of which the mummies have been found in Egypt. As a living inhabitant of the world, however, its history is of very little importance.

THE RAT-TAILED SHREW (*S. myosurus*) is a species which appears to rest on very doubtful authority, and even its native country has not been clearly ascertained. It is described as having the muzzle thick, the tail round and quite naked of fur, and the fur on the body entirely white. The authorities are not altogether agreed about it; for some say that both sexes are white; while others say that only the female is white, while the male is brownish grey. The probability is, that the white ones are merely albinos, and that the absence of hair on the tail is also accidental.

Besides those which we have enumerated, many other shrews are mentioned by authors, and there are probably many more that have not been noticed; but the history of the shrews is one of the most incomplete in the whole range of the mammalia. That they are very singular animals, and very generally distributed, is well known; but their habits are so obscure that half of even the little that is said respecting them rests very much on conjectural foundations.

SIALIS (Latreille). A genus of neuropterous insects, forming the type of the family *Sialidae*, having the antennæ simple and filiform, the mandibles of moderate size, and the wings laterally deflexed when at rest. The type is the *Hemerobius lutearius* (Linnaeus), a very common sluggish insect found in the early spring months in the neighbourhood of water, and by some persons regarded as the May-fly of the angler. It is of a dull blackish colour, with brown wings. The female deposits an immense number of eggs, which she attaches to different aquatic plants, or other matters near water, in which the larvæ reside, where they swim very slowly. When full-grown they leave the water and burrow into the earth at the edge of their former abode, where they undergo their transformations, the pupa being inactive.

The other genera belonging to the same family are *Corydalis*, having very large mandibles, composed of a North American species, and *Chauliodes*, having pectinated antennæ.

SIBBALDIA (Linnaeus). A genus of hardy trailing shrubs and perennial herbs, belonging to the fifth class of Linnaean botany, and to the natural order *Rosaceæ*. The *S. procumbens* is British, and found on northern mountains.

SIDA (Linnaeus). An extensive genus of herbaceous annuals and perennials, shrubs and under-shrubs, natives of many tropical countries. The flowers are monadelphous, and the genus belongs to *Malvaceæ*. The genus is separated into four divisions, and many sections. They are free flowerers, and frequently ripen seeds in the stove; by which they are increased, or by cuttings.

SIDERITIS (Linnaeus). Shrubs, under-shrubs, and herbaceous perennials, mostly natives of Europe,

belonging to the natural order *Labiata*. These are the Ironworts of English authors, grow in any common soil, and are propagated by cuttings.

SIDERODENDRON (Jacquin). The Iron-tree of the West Indies, belonging to *Rubiaceæ*. It is valued for its timber, which is remarkably hard and durable. The plant is kept in the stove, and is propagated by cuttings.

SIEVERIA (Willdenow). A genus of herbaceous plants found in the northern parts of Europe and America. They belong to *Rosaceæ*, delight in a dry sandy soil, and are increased by division or by seeds.

SIGARETUS (Lamarck; *HELIX HALIOTIDÆA*, Linnaeus). This mollusc is concealed in the mantle of the animal producing it. It somewhat approximates the *Natica*, greatly resembling a very depressed shell of that genus, from which, however, the extraordinary width of the aperture, and its spiral short columella, render it perfectly distinct. This shell is nearly orbicular, but subauriculated, and very much depressed. The left side short and spiral; the spire flat; the aperture oval, entire; extremely wide, and exposing the whole of the interior; there are two lateral internal muscular impressions. But a few species of this genus are known, and their habitat appears unconfined to any particular sea. About three species are known in a fossil state.

SILENE (Linnaeus). A very extensive genus of annual and perennial herbs, mostly European. The flowers are decandrous, and the plants belong to *Caryophylleæ*. From the gumminess of some of the flowers flies are entrapped. Hence the vulgar name of catchfly. By far the greater number of the species are mere weeds, but some of them are highly ornamental.

SILICULARIA (Lamarck; *SERPULA ANGUINA*, Linnaeus). Linnaeus classed this mollusc with the genus *Serpula*; but a more careful examination than he bestowed having been made by subsequent naturalists, points out distinctions sufficiently marked to constitute a separate genus. The shell is tubular, very irregularly twisted; sometimes in a spiral form at the base; open at the upper extremity, and having a subarticulated longitudinal dentated fissure the whole of its length, or sometimes closed at a short distance from the summit. The substance of the shell is thin, the aperture round, and the edges sharp. Their habitat is the Indian ocean, and some species are found in a fossil state.

SILK COTTON TREE is the *Bombax ceiba* of Linnaeus. It is so called because the seeds are enveloped in a downy substance like silk. The substance serves for stuffing mattresses in India, and has been tried to be worked by both spinners and haters, but the fibre is found not to be of sufficient tenacity for such fabrics.

SILK-WORM. The ordinary name of the caterpillar of a lepidopterous insect belonging to the section *Nocturna*, and family *Bombycidae*, and systematically known under the name of *Bombyx Mori* of Linnaeus, or the mulberry-tree moth, which, in the winged state, is of a cream-colour, with several transverse bands of a darker colour across the anterior wings, and a crescent-shaped central mark. The caterpillar, when full-grown, is nearly three inches in length, and is too well known to need any particular description. The eggs, when good, are of a pale slate or dark lilac colour; they may be purchased in

Covent Garden market at 10s. per ounce ; and care should be taken to obtain them of the proper colour, because those which are of a pale yellow colour are imperfect. The caterpillars are very voracious, as may be observed from the observations of Count Dandolo, given in our article *INSECT*, vol. ii. p. 837. During this period of its existence it undergoes four moultings, which succeed each other at certain intervals, dependent upon the temperature of the weather, or of the places in which the caterpillars are kept, as well as upon the quality and quantity of their food. Thus, if the worms be exposed to a temperature of 80° to 100° Fahrenheit, the moultings will be hastened, and not more than five days required between the third and fourth moultings ; whereas if the temperature be reduced, seven or eight days will be required. The period of the moultings is also regulated by the temperature at which the eggs have been kept during the winter. When the heat has been regulated, the first moulting takes place on the fourth or fifth day after hatching ; the second in four days more ; the third in five or six days more ; and the last in about eight days. Ten days more are required after this moulting, so that in about thirty-two days after hatching the caterpillar has attained its full size. —Rozier, *Cours d'Agric.* Paris : 1801. *Ins. Arch.* p. 318.

When full grown the caterpillar commences the spinning of its cocoon ; and it is this construction which is subsequently employed in the manufacture of silk, as will be more fully shown in the subsequent part of this article. The silk is elaborated in two long slender vessels lying at the sides of the stomach and intestines, and terminating in a single tube, through which the viscid fluid, of which the silken threads is composed, is forced by the peristaltic action of the muscles. This tube terminates in the centre of the lower lip of the caterpillar. Although, however, the two vessels unite into a single tube, it is evident that the silken threads are not united, since we learn from the recent microscopical investigations of Dr. Ure, (*Trans. Ent. Soc.* vol. i., *Journ. of Proceedings*, p. 50.) that each of the silk threads was found to be composed of two distinct cylinders, which in good silk are found to be perfectly parallel, and quite cylindrical. The unevenness or the want of parallelism producing inferiority in the raw material. Each of these cylinders varies in diameter from one-two thousand two hundredth part of an inch (the measure in silk of the best quality), to one-eighteen hundredth of an inch. When imported, however, several distinct threads are found to be reeled together, which is done by the grower of the silk-worms, the threads being passed through several eyelets, and then wound off. The imported raw silks are of various qualities, depending upon the mode and time of feeding, as well as upon the food of the silk-worms. These compound threads are one-five hundredth part of an inch in diameter, each being divisible into eight threads ; that is, into four pairs of cylinders in the best silk. The specific gravity of silk is, according to this author, greater than had been generally considered, being 1256 to 1000, and consequently greater than the strongest muriatic acid or water.

The cocoon consists of three distinct layers of silk ; the first is loose and flossy, and is unserviceable for the silk manufacture ; the second is closer, the silk crossing from side to side ; and the third is still finer, and is glued strongly together, so as to form a

compact inner coating ; of course the more silk which is employed in the construction of the outer floss covering, the inner coatings are diminished in thickness ; and, acting on this principle, M. Hoffmann, of Munich, has informed the writer hereof that he has succeeded in obtaining considerably more than the ordinary supply of the middle layer, by placing the worms, when full grown, in very confined situations, their instinct informing them that, in such case, there is no necessity for a floss coating of the ordinary thickness. When this cocoon is completed, the inclosed caterpillar again casts its skin, with the head and jaws attached to it, when it appears under the form of a conical chrysalis of the ordinary shape. At first the chrysalis, when opened, appears to consist only of a yellowish mucus, but by degrees the various parts of the future moth acquire their proper consistence ; and in about a fortnight or three weeks a slight swelling of the chrysalis indicates the approach of another change ; a rupture down the back succeeds, and, by degrees, the moth bursts through its horny coating into the hollow chamber of the cocoon. The moth subsequently emits a fluid, which has the effect either of dissolving the gum or the threads at one end of the cocoon, and soiling that part where the moth makes its escape. This of course is a circumstance which would be injurious to the interest of the silk grower, and is remedied in the manner subsequently described. Previous to the egress of the perfect insect, the cocoon may be wound off without any interruption of the thread, so that it is evident that the whole is spun continuously by the caterpillar ; the length of the thread in a cocoon varies from six hundred to a thousand feet, and the whole does not weigh more than three grains and a half—ten thousand cocoons scarcely averaging so much as five pounds in weight. An ounce of eggs will produce about 40,000 caterpillars, which will consume 1073 lb. of leaves, and produce from 80 to 100 lb. of cocoons, or about 8 lb. of raw silk.

The perfect insect is remarkable for its dull and stationary habits ; indeed, it can scarcely be said to possess the powers of flight. In this respect a similarity of manners exists also in the caterpillar, which does not wander away from its food, although unconfined ; and it has been well remarked by Mr. Sella, that these interesting peculiarities materially favour the easy management of the insect, and beautifully harmonise with the consideration of its vast importance to mankind.

The history of the silk manufacture, and its introduction into this country, require some notice in a work like the present. The insect is an inhabitant of China, although now perfectly naturalised in other countries ; and the Chinese are supposed to have discovered the art of making silk 2700 years B.C., when the Empress Si-ling-chi is said to have first observed the labours of the silk-worms on wild mulberry-trees, and applied their silk to use. From China the art passed to Persia, India, Arabia, and the whole of Asia. According to Latreille, the city of Turfan, in Lesser Bucharía, was for a long period the rendezvous of the caravans coming from the East, and was the chief depôt of the silk-trade of China. It was the metropolis of Sere, in Upper Asia, or of Serica of Ptolemy. The expedition of Alexander into Persia and India first introduced the knowledge of silk to the Grecians, 350 years B.C., and, with the increase of wealth and luxury in the Grecian court,

the demand for silk prodigiously augmented. Thence it passed to Rome, probably about the time of Pompey or Julius Cæsar, the Emperor Heliogabalus, about 220, being the first emperor who wore a robe entirely of silk. Until about the beginning of the sixth century, silk in the raw state had alone been seen out of China, the exportation of the insects from China being prohibited under pain of death, and up to this period the real nature of the material was unknown. By some it was supposed to be a kind of fleece which grew upon the branches of trees, by others the bark of the tree itself; by some as the production of a flower; by others as the production of a shell-fish similar to a mussel; by others as the entrails of a sort of spider, which was fed for four years with paste, and then with the leaves of the green willow, till it burst with fat; and by others that it was the produce of a worm which built nests of clay and collected wax. But at that period two monks, under the persuasions of the Emperor Justinian, contrived to bring some eggs from China, hidden in the handles of their pilgrim's staves, having also obtained a thorough knowledge of the art of rearing the worms and manufacturing the silk. The eggs thus obtained were hatched in a hotbed, and being afterwards carefully fed, the experiment was fully successful, and the silk-worm became generally cultivated through Greece. In 1130, the growth of the white mulberry, and the removal of many of the silk growers from the Peloponnesus to Sicily, was effected by King Roger, which island became the great mart of nearly all the silk employed in Europe. In 1440, the white mulberry was first introduced into Upper Italy; and under Charles VII. the first tree of this kind was planted in France, where silk manufactures were established in 1480 at Tours. The great Henri Quatre greatly exerted himself to promote the culture of the silk-worm through his dominions; and a plantation of white mulberry trees was made in the garden of the Tuilleries, where a large building for the silk-worms was erected. By degrees the growth of the mulberry, and the rearing of the silk-worm, was tried with various success in different parts of Europe. At present the silk manufactures of France constitute a very important part of her commerce; and some idea may be formed of the silk goods annually sent to England from that country, by the fact, that the quantity on which duty was paid, from 1688 to 1741, averaged 500,000*l.* a-year. Notwithstanding, however, the great quantity of silk now raised in France, the manufacturers of that country still import to the annual value of 30,000 francs of raw silk from Piedmont and Italy.

In our own country, silk, up to the beginning of the sixteenth century, was scarcely known. At that period, however, it appears to have found its way to England more plentifully from France; for, although the silk manufacture had been introduced into this country in the fifteenth century, we find that Henry VIII. had the first pair of silk stockings ever seen in England, sent to him from Spain; and a similar present was made to Edward VI. by Sir James Gresham. In the reign of Queen Mary, however, an act was passed with the view of entirely discountenancing the importation of this article of luxury, and of assisting the consumption of our own productions, which enacted, that "whoever shall wear silk in or upon his or her hat, bonnet, or girdle, scabbard, hose, shoes, or spur-leather, shall be imprisoned during

three months and forfeit ten pounds." The long and quiet reign of Queen Elizabeth which succeeded, together with the influx of the Flemings, occasioned by the disturbances in the Low Countries, gave a powerful stimulus to the silk manufactures of England. But it was in the next reign that a still greater impulse was given to them by James the First, who not only issued an edict recommending the cultivation of the silk-worm, and offered packets of mulberry seed to all who would sow them, but also planted these trees to a great extent himself, and established silk-worm houses as we learn from the two following entries in the issues of the exchequer during his reign. In the first, dated Dec. 5, 1608, payment was directed to be made of the "sum of 935*l.* for the charge of four acres of land taken in for His Majesty's use, near to his palace at Westminster, for the planting of mulberry-trees, together with the charge of walling, levelling, and planting thereof with mulberry-trees;" and the second, dated January 23, 1618, nine years subsequently, directing payment to be made of 50*l.* "for timber-board, glass, and other materials, together with workmanship for making a place for His Majesty's silk-worms, and for making provision of mulberry-leaves for them." Letters were also issued by this prince to the lord lieutenants, recommending the planting of mulberry-trees, and offering them at two farthings each. Although this attempt to introduce the growing of silk-worms into England proved unsuccessful (the reason whereof appears clearly to have been that the black mulberry was distributed instead of the white); the manufacture of silk had become so extensive, that in 1666 (tem. Carol. II.), not fewer than 40,000 individuals were engaged therein. In 1685, the prosecution of the Protestants in France drove above 50,000 French artisans to this country, by which the trade was still further greatly increased. These refugees chiefly settled in Spital-fields, which part of London has since been the headquarters of the silk weavers in this metropolis. Notwithstanding this increase, the importation of silk in the manufactured state was very great, as from 1685 to 1692, from 600,000*l.* to 700,000*l.* worth was annually imported. In the latter year the refugees obtained an exclusive patent for certain articles; in 1697, parliament prohibited the importation of French and other European silk goods; and in 1701, the prohibition was extended to Chinese and Indian manufactures. From this period the silk manufacture has become a very important branch of commerce of which it would be here out of place to pursue the history. It will suffice in order to show the present state of the English manufacture, to state that in the year 1838, the quantity of silk imported for home consumption was more than four millions and a half pounds weight; whereas in 1814 it was only 1,580,000 lbs.; and in 1823, 3,650,000; and at the present time probably 700,000 persons are engaged in it. (Hope in Trans. Ent. Soc. 1, p. 124).

It remains, however, to notice, as connected with the natural history of the insect in connexion with its commerce, that in 1825, a company was established under the name of "The British, Irish, and Colonial Silk Company" with a large capital and under the direction of the celebrated Count Dandolo, whose Treatise on the Management of the Silk Worm is considered the best work on the subject in Italy. Extensive plantations were formed near Slough, in Devonshire, and near Cork in Ireland; but after

numerous trials, it was found that the climate of the British Isles was too humid for the production of useful silk, and the company was finally broken up. It has been observed, by way of accounting for the failure of this and other undertakings of a similar nature in this country, that although "the mulberry-tree is found in different climates; yet the juice of the leaves grown in the north is much less suitable for the production of good silk than that of the south. In this respect the mulberry-leaves and silk differ as much as wines according to the climate and soil in which they are produced. In general, every climate and soil that will grow good wheat will produce large succulent mulberry-leaves; but these leaves will, in many cases, be too nutritive; that is, they will have too much sap and too much substance and succulency. The wild mulberry with smooth leaves answers better for such a soil than the grafted mulberry with large leaves. A general rule, and one to be depended on is, that the mulberry, to produce the best silk, requires the same soil and exposure that the vine does to produce the best wine. Experience has proved that silk-worms nourished by leaves gathered from a dry soil succeed much better, produce more cocoons, and are less subject to those diseases which destroy them, than those which have been nourished by leaves produced by an extremely rich soil."—(Journ. d'Agric. des Pays Bas, quoted in Arboretum Britannicum, from which some of the preceding historical details have been abridged.) How far these objections are entitled to full weight, and how far any other plans (such as those suggested by the Rev. F. W. Hope in a Memoir upon Silk Insects, contained in the first volume of the Transactions of the Entomological Society) may succeed in this country, must be determined by future experiments; in the mean time it is certain that the severity of the climate cannot be an obstacle: even the climate of Pekin or China is much severer than that of Scotland; and that in America not only has the growth of the silk been effected, but double crops in the course of a single season have been obtained. It is objected, however, that the number of hands requisite, and the high rate of wages in this country, would be an obstacle; but children and old persons might be employed, especially in the rearing houses, which should be kept at a certain temperature.

A short account of the plans adopted in rearing the silk-worms in an artificial state will close our account of the *Bombyx mori*. Instead of the eggs being allowed to hatch at their own fixed time, they are preserved in a temperature of from 55° to 60° Fahr. To hatch them a temperature of 86° Fahr. is required, so that heated rooms are necessary; but in the southern parts of China, the East Indies, &c., the natural temperature of the air is sufficient for this purpose. The houses in which the insects are kept are built with numerous windows for the admission of air, and furnished with tables or shelves on which the insects are kept; these shelves have moveable ledges of an inch or more in height to secure the insects, and several stages are arranged one above another, care being taken to place them at a distance from the wall, so as to ensure a free current of air, which is essentially requisite, as well as great cleanliness in the removal of dead and unconsumed leaves and other litter. Indeed, the great care required to preserve them clean and warm is curiously shown in the following extract from an old Chinese work upon

the subject:—"The place where their habitation is built must be retired, free from noisome smells, cattle, and all noises; a noisome smell, or the least fright, makes great impressions upon so tender a breed; even the barking of dogs and the crowing of cocks are capable of putting them in disorder when they are newly hatched. For the purpose of paying them every attention an affectionate mother is provided for the worms, who is careful to supply their wants; she is called *I-san-mon*, mother of the worms. She takes possession of the chamber, but not till she has washed herself, and put on clean clothes which have not the least ill smell; she must not have eaten any thing before, or have handled any wild succory, the smell of which is very prejudicial to those tender creatures; she must be clothed in a plain habit without any lining, that she may be more sensible of the warmth of the place, and accordingly increase or lessen the fire; but she must carefully avoid making a smoke or raising a dust, which would be very offensive to these tender creatures, which must be carefully humoured before the first time of casting their slough." During the first twenty-four hours of the creatures' existence, the patient Chinese feeds the objects of her care forty-eight times a day, or once in every half hour; during the second day and night thirty times, and so on, reducing the number of meals as the worms grow older.

According to Count Dandolo, 39,000 eggs weigh an Italian ounce: five ounces produce from 150,000 to 195,000 silk-worms. These require 8250 lbs. of grafted mulberry-leaves, and will produce 600 lbs. of cocoons, which in common years will sell for 1000 Milan livres. In Persia silk-worms are permitted to feed upon the boughs of the trees as well as the leaves; and it is asserted, though perhaps too loosely, that in some countries of the south of Asia, no less than twelve crops of cocoons are obtained in a year; whereas in Europe only one crop is capable of being produced. That crop, however, is so much more abundant, that Count Dandolo is of opinion that one good European crop equals in point of produce all the crops of Asia.

Soon after the cocoons are completed, a certain quantity is set apart for breeding, and the rest are used for silk, the enclosed insects being first destroyed, either by exposing the cocoons to the sun for three days when the temperature is not below 86° Fahr., or by being placed in ovens heated to the same temperature, or by placing them over the steam of boiling water or spirit. The floss silk is then removed, and the cocoons thrown into water, which then is almost suffered to boil, by which process the gum is dissolved, and the fibres of the silk loosened, so that the reeling of the silken thread is rendered very easy.

The following short estimate of expenses occurring in the produce of five ounces of eggs will give an idea of the proceedings of the silk-grower:—

	Milan Liv. Scs
Five ounces of silk-worms' eggs . . .	15 0
Fuel wood for hatching them . . .	1 15
8250 lbs. of leaves . . .	885 0
Expense of gathering the leaves . . .	96 5
Shavings . . .	16 9
Faggots and broom . . .	22 10
Paper . . .	18 0
Oil for lamps . . .	9 0

Fumigating-bottle	1 10
Day labour, men and women	109 0
Total	674 0
Ground rent and interest of capital	90 0
	<hr/> 764 0

which sum being subtracted from 1568. 18. the value of 600 lbs. of cocoons will leave a net profit of 799 livres (thirty of which equal a pound sterling).

In India considerable quantities of silk are obtained from the cocoons of several large species of moths belonging to the genus *Saturnia*: of these the most important are the Tusseh, Arrindi, Bughy, and Koligurra silk-worms; of the two former of these an interesting memoir is given by Dr. Roxburgh in the Linnæan Transactions, and of the last by Lieut. Col. Sykes in the Transactions of the Royal Asiatic Society. The Tusseh worms are the caterpillars of the *Saturnia Paphia*, Linnæus, and are found in such abundance in the neighbourhood of Bengal as to afford a constant supply of very durable coarse dark-coloured silk, which is woven into a cloth much worn by the Brahmins and some other sects, and which is of so great durability, that after nine or ten years' wear it does not show any signs of decay. The Arrindi silk-worm is the caterpillar of the *Phalæna Cynthia*, Drury, and feeds on the leaves of the *Palma-Christi*; its cocoons are exceedingly soft and flossy, so that it is impossible to reel it off, it is accordingly spun like cotton, and the thread thus manufactured is woven into a coarse white cloth of loose texture, but of such considerable durability, that the life of a single person is seldom sufficient to wear out a garment made of it. It is used not only for clothing, but for packing fine cloths, &c. (Introd. to Ent. i., p. 396).

SILPHEUM (Linnæus). A genus of North American perennial herbs, belonging to *Compositæ*. They are tall-growing plants, and suitable for the interior of shrubberies, and are increased by division.

SILPHIDÆ (Leach). A family of coleopterous insects belonging to the section *Pentamera*, and subsection *Necrophaga*, having five distinct joints in all the tarsi, and the mandibles terminated in an entire point, and not notched. The antennæ often terminated in a perfoliated mass of four or five joints; the maxillæ often armed with a corneous tooth; the anterior tarsi are often dilated, and the elytra are in general furnished with a raised lateral margin. These insects are generally of obscure colours, and subsist upon carcases, bones, and other putrefying matters, they are consequently of great service in removing much infectious matter, which might otherwise render the atmosphere unwholesome. The larvæ reside in the same situations, and are furnished with six legs, and two or more anal appendages. The genera are *Necrophorus*, *Necrodes*, *Oiceoptoma*, *Silpha*, *Phosphuga*, *Agyrtes*, *Peltis*, *Spherites*, and *Necrophilus*; those printed in italics being inhabitants of this country. The most interesting genus is that which contains the sexton beetles *Necrophorus*, which see. The genus *Silpha*, as now restricted, comprises those species which have the antennæ gradually clavate, the club being four-jointed, the elytra rounded behind, and the body depressed and shield-shaped. The majority of the species are black or pitchy in their colours, and frequent carrion, &c.;

but in the *Silpha quadrimaculata*, Linnæus, the thorax and elytra are pale, buff-coloured, with black spots; and, in accordance with its various hues, it is found in trees, amongst the foliage of which it lurks about for the purpose of seizing upon and devouring lepidopterous caterpillars.

SILVER. This valuable metal occurs in many parts of the globe, and in a variety of combinations. Native silver has the general characters of the pure metal. It is found in masses, sometimes ramifying into arborescent and capillary forms. At other times it is crystallised in cubes and octohedra. The richest known mines are found in Peru and Mexico. Europe also presents some valuable mines, but they are principally confined to Saxony, Bohemia, and Norway. It is true that both Cornwall and Devonshire present some fine specimens, but silver can hardly be placed amongst the mineralogical treasures of this country. It may, however, be proper to add, that silver was once found in considerable quantities in Stirlingshire, but the vein has been long exhausted.

SILURUS, or rather **SILURIDÆ**, a family of fishes which have no English name, nor is there any well-authenticated account of even a single specimen occurring in any part of the British islands, though Sir Robert Sibbald names it in his Appendix to the River Fishes of Scotland; and subsequent writers upon British fish have, upon this authority, included it in their lists.

The *Siluridæ* are soft-finned fishes with abdominal fins, and in Cuvier's arrangement they follow immediately after the pike family. They are very peculiar fishes, and may be looked upon as the family in which a section of the abdominal finned fishes terminates. They are wholly fresh-water fishes, or, at least, the only sea in which they have been found is the Baltic, and it contains much less salt than the ocean generally, and so little indeed in some places as to be available for culinary purposes. Generally speaking, they are of clumsy and unwieldy form and size. They chiefly inhabit the mud at the bottom of rivers and some lakes, but mostly the former; and their powers in swimming are sluggish, and performed by the flexures of the body, in the manner of those of an eel, rather than by the simple but vigorous action of the caudal fin. The character of their flesh corresponds with this sluggish habit, for, though generally of good flavour, it is too rich for being easily digested. They also accumulate a great deal of fat, and the fat upon them has some slight resemblance to the lard of pigs.

There is only one species found in Europe, and that chiefly in the larger rivers of the north, especially those which discharge their waters into the Baltic. But in the rivers of the warmer climates, especially in those of Africa, they are much more abundant both in numbers and in species; and they were placed among the sacred fishes by the ancient Egyptians. They are exceedingly voracious; but, in consequence of the inferiority of their swimming powers, they are unable to capture prey by chasing it, and therefore their habit is to lie in wait, and seize their food by surprise. As is the case with most, if not all, of the lurking fishes which wait at the bottom for such prey as may swim over them, they are furnished with barbules or feelers, which vary in number in different members of the family, but of which two in the upper jaw are generally in so far supported by the maxillary bones, by means of which

they have a considerable degree of motion. It is understood that these barbules are made use of as baits, or rather as lines for the fish, and that the points of them moving about in the water, while the fish is either covered with mud, or undistinguishable from it in consequence of its dull colours, is quite unobserved, until the prey is within reach of its great mouth, which is semicircular, and opens upwards rather than otherwise, the under jaw being a little longer than the upper one. The *Silures* are so large and powerful, that they have little danger to fear from any other inhabitant of the waters; and some of them, besides having a mouth sufficiently capacious for swallowing any ordinary fish, have a very formidable spine in the front of the dorsal fin, with which, as it is ragged and toothed in the sides, they can inflict very serious and even dangerous wounds.

The characters of the family are: the skin of the body covered with a slimy secretion, and without any true scales, though some of them have it covered with large bony plates; their intermaxillary bones are suspended under the ethmoid, and form the edge of the upper jaw; and the maxillaries are only rudimental, or produced to support those barbules of which mention has already been made; the intestinal canal is large, with many flexures, but without any cæcal appendages; the swimming-bladder is large, heart-shaped, and supported by peculiar bones; very generally the dorsal and the pectoral fins have a strong articulated spine for their first rays, and not unfrequently there arises behind the dorsal a second one, of an adipose or fatty consistency, as in the salmon family.

Taken as a family, the *Siluridæ* are exceedingly numerous, and varied in their characters. Cuvier divides them into four principal genera, *Silurus*, *Malapterurus*, *Aspredo*, and *Loricaria*, and of these, especially the first, there are very many subdivisions. It would far exceed our limits to enter into the details of them, and for popular purposes this is not necessary, inasmuch as their history is exceedingly obscure, and they have no interest whatever to the English reader. We shall therefore only mention a very few particulars respecting the species found in Europe, and give simply the generic distinctions of the others.

SILURUS. The fishes of this genus are exceedingly numerous, and require subdivision into many smaller sections. Their general characters are: the body clammy and without any scales; the mouth is at the extremity of the muzzle, or a very little turned upwards, and in the greater number of the subgenera there is a very strong spine answering to the first ray of the dorsal fin. This spine is articulated upon the bones of the shoulder in such a manner as to be moveable not only in the direction of the mesial plane of the fish, but also laterally. This spine is a very formidable weapon. In a large fish it is of considerable size, and the sides of it are ragged with teeth, so that it tears and lacerates in the most painful manner. As is the case with the spines on the bodies of many fish, it is often supposed to be impregnated with a poison; but there is no reason to believe so; for the mechanical injury which it is capable of inflicting is serious enough, and there is no doubt that it is quite competent to occasion lock jaw in those who have the misfortune to be wounded by it. It may not be useless to the public to mention, that, in the translation of Cuvier's *Animal Kingdom*,

purporting to be done by "EDWARD GRIFFITH, F.R.S., &c., AND OTHERS," there is a very curious "doing into English" of the original text of that most observant and accurate Frenchman. Cuvier says, "et il y a très souvent en arrière une adipeuse comme dans les saumons," which the learned persons have rendered, "and there are often three more behind an adipose, as in the salmones." This translation, which repays the French rendering of "Love's last Shift," by "La dernière Chemise de l'Amour," or any other that has been or can be done or imagined, shows pretty clearly how large a licence may be taken by any man who can, by hook or crook, contrive to

"Shine in the dignity of F.R.S.;"

for, assuredly, if any mere mortal, unprotected by the coat of darkness which these mystic letters are supposed to wrap round their possessor, had dared thus to translate Cuvier, the naturalists and the critics would have been down upon him *en masse*, scalpel and scalping-knife. Such, however, is the fact, as any one may see by turning to p. 399 of the account of fish; and it is pretty clear that the parties, that is, the F.R.S. and others, must have become Homerised on the occasion, and "*nodding* at their duty." In the preceding part of the sentence Cuvier is speaking of the dorsal spine and the spines of the pectorals; and no person upon earth who should happen to read the translation, without having seen the original, could avoid concluding that the fishes have three *spines* more behind an adipose, though an adipose *what* is not said. What Cuvier does say is not that there are three spines in addition to the dorsal and pectoral ones behind an adipose, or behind any thing else; he merely says that there is very often an adipose dorsal-fin behind the rayed dorsal, as is the case in the salmon family, not the "salmones," which are fishes quite unknown to British ichthyologists, or even mentioned in Mr. Yarrell's work, minute and perfect as that work is. They have the head flattened, and the intermaxillary bones suspended under the ethmoid, and not protractile. The maxillary bones are very small, and in almost every one they terminate in fleshy barbules, more or less elongated; and there are other barbules, sometimes attached to the under jaw and sometimes to the nostrils. They have a gill-lid, but no gill-flap, from which it is inferred that they have but a limited respiration, and such a respiration accords with their sluggish habits, and their lurking at the bottoms of the rivers. Their air-bladder is very strong and heart-shaped, and the possession of such an organ by fishes that very seldom quit the bottom of the water is a proof that the common supposition, that it is useful in changing the specific gravity of the fish, is by no means well founded. The stomach is a simple cul-de-sac, and the intestine, though long, is without cæcal appendages. The rivers of the warm countries are their principal habitats. Though they are in general feeders upon animal matters, they are not exclusively confined to these, for they are understood to eat both the succulent roots and the seeds of plants, the latter of which have been often found in their stomachs. It is to be regretted that so little is known of their habits and their use in the economy of nature, as there is no doubt that, from their numbers, their size, and the places in which they are found, the part which they perform must be an important one. They are fishes of the beds of the rivers, only found in

those which are of large size, and they do not appear at the surface, or near the banks, except at the time when they spawn, which occupies about two months out of the twelve. In some of their habits they appear to resemble the eels, but the resemblance does not extend so far as the migratory habit of the latter; for it does not appear that the *Siluri* ascend or descend the rivers for any seasonal purpose, their principal motion being from the bed of the river, in order to deposit and fecundate their eggs, and back again when that object is accomplished. Cuvier divides them into nine subgenera, and some of them admit of a second subdivision. They all have the dorsal-fin forward on the body, and composed of but few rays, but the anal extends over a very considerable length of the under side, and reaches nearly to the tail.

SILURUS properly so called. These have the dorsal-fin very small, and without any sensible spine in the first ray. Their teeth on the jaws are arranged like those of a card, and they have a third band of teeth upon the vomer. They are found in various parts of the world, but chiefly, if not exclusively, in Europe and Asia. The European one, and it is the only European member of the family, is the

The Sly Silurus (Silurus glanis). This, in as far as appearance is concerned, is a very ugly fish, lazy and lumbering in its form, and repulsive in its appearance. It is dark in the colour, and is altogether of a slimy character; while the flat head, the curious semi-circular mouth, the long barbules, and the small and projecting eyes, give it an aspect very unlike that of almost any other fish.

The head is shovel-shaped, flat, and the colour is of a deep green; the mouth very wide and deep; the jaws are circular; the lowest one the longer, but both are furnished with a number of incurved teeth; there is a long barbule on each side of the upper lip; the nostrils are round, and placed between these long barbules; the eyes are behind them, small, the pupils black, and the irides white; the back is of a deep green, and round; above the lateral line the sides are of the same colour, a fainter shade of green below it; and the body is covered with dark spots of no very definite shape; the body is long and thick; the belly short and expanded, and of a light yellow colour; the body is covered with slime; the pectoral-fins are deep blue at the base and at the extremities, the middle parts yellow; the first ray bony, strong, and serrated on the inner surface; the dorsal and ventral fins are yellowish at the basal part, and bluish towards the ends, and both are placed much nearer the head than the tail; the anal-fin is long, the tail rounded, and both are of a grey yellow, with lilac coloured or violet edges; the fin-rays, in number, are five in the dorsal, eighteen in each of the pectorals, twenty-four in the anal, and seventeen in the caudal.

It is a fish which is described as inhabiting many countries, but it is doubtful whether those of the tropical rivers, and also of the rivers of America, may not be different from the one which is met with in Europe. That they are different is rendered more probable by the fact that the European one is found in the rivers of the cold parts of the country rather than in the more southerly and western ones; and it is natural to conclude that, if a fish were common both to Europe and to Africa, it would be most abundant in those rivers of Europe which are nearest to Africa, and fall into the Mediterranean. Now, as

a European fish, we believe that the *Silurus* is almost, if not altogether, unknown in the rivers of Spain, of Italy, and of the south of France, or indeed in any river of the last mentioned country; whereas it is abundant, and grows to a large size, in the rivers which fall into the Black Sea and the Baltic, even as far north as Sweden. Specimens have been mentioned in the north weighing seventy or eighty pounds, and it is in these northern countries chiefly that it is valued as an article of food. It is generally admitted, however, that, though its flesh is not disagreeable to the taste, it is in all cases difficult of digestion.

It is described as being a dull and sluggish animal, forming holes for itself in the soft mud, in which holes it spends a great part of its time lying in wait for its prey, and in general escaping observation. We have already mentioned the manner in which the barbules are supposed to attract the smaller river fishes so as to bring them within its reach. They have very much the form of worms; and, as the fish keeps them in pretty constant motion, one can easily understand how the fishes may be attracted by them. When the rivers are swollen and foul, it is said to be more active, to come out of its hiding place, and range about in its slow way in search of food. This is a habit with very many of the ground fishes, and river fishes generally are most on the alert when the water of the rivers is in a state of agitation. It is most frequently seen in the spring, at which time of the year the males and females come together towards the banks during the heat of the day, and for the purpose of spawning. The eggs are of a greenish colour, not very numerous in proportion to the size of the fish, and it is ascertained that they are hatched in the course of about eighteen days. This fish is called *Saluth* by the Swiss, *Wels* and *Scheid* by the Germans, and *Mal* by the Swedes. In the latter country it is dried for winter food, and the fat is made use of separately, being more like the soft fat of some of the mammalia than the common oil of fishes. There appear to be different species of this fish in the northern parts of the eastern continent, or else those which inhabit different rivers vary in their appearance. Some are also found in the fossil state, which is what we might be prepared to expect in fishes that lurk in the mud at the bottom of rivers, and which must be occasionally buried in the rubbish brought down by the floods. The particulars of these are, however, not worth stating, as the fishes have no history of a popular nature, and the one of which we have given some particulars has not much.

From the little action of these fishes, it will readily be understood that they are long lived; for it is a general law among vertebrated animals, that sluggish action and longevity go hand in hand; and the accumulation of fat is also a concomitant of the other two. It appears also that these fishes continue increasing in size for a very long period of years, and that, in fact, the time when they cease to grow and begin to feel the effects of old age is quite indeterminate. They grow to a much larger size than any other fish of the fresh waters of Europe; for although, as has been mentioned, seventy or eighty pounds in weight is a sizeable fish, individuals far heavier than that are occasionally to be met with. Some of these are as much as twelve or even fifteen feet in length, and weigh from three hundred pounds to four hundred. Some of the largest that are recorded wer

taken in the Oder. When they are once discovered they are not very difficult to capture, as their motions are slow; but they are very tenacious of life. It does not appear that they can be introduced with success into any rivers except those in which the water is very cold, which is an additional reason for concluding that they are not the same species which is met with in the warm countries.

Schilbeus. This is one of the subdivisions of the genus *Silurus*, and it occurs chiefly in the Nile, where there are two species, both much sought after on account of the flavour and wholesomeness of their flesh. Their characters, as distinguished from the European species, are: the body compressed vertically; the head small and depressed; the neck rising suddenly to a considerable elevation; the eyes very low, giving a singular expression to the head; the lips furnished with eight barbules, four on the extremity of each jaw; and the spine of the first ray of the dorsal very strong and toothed. There are at least two species in the Nile, the one called *Schilbé* by the Arabs, and the other *Schilbé oudney*, which last word means eared; and the systematic name is only the Arab one with a Latin termination. The chief distinction of the two species is that the first has seven rays in the dorsal, eleven in each of the pectorals, six in the ventrals, sixty-five in the anal, and eighteen in the caudal; while the second has eleven in the pectoral, six in the ventral, seventy-seven in the anal, and eighteen in the caudal. They appear to live more indiscriminately in fresh and salt water than the *Silurus* of Europe; for, according to the accounts, they are found in the Red Sea as well as in the Nile, and the Red Sea receives a smaller supply of fresh water than any other sea of the same extent; but, at the same time, it is one of the most productive of animal life any where to be met with on the surface of the globe. There appears to be an American species of this genus, which has the head small and blunt, and the eyes so very minute that they are hardly visible.

Mystus. The fishes of this subgenus are mostly found about the mouths of rivers in the tropical seas, especially in the Atlantic. They are covered with a smooth naked skin without any armature on the sides; and they have an adipose dorsal fin behind the one with rays. They are very common about the mouths of the rivers in the West Indies, and on the north coast of South America.

Pimelodus. These have the skin soft and smooth, and they are without teeth on the vomer, but they have some on the palatal bones. They vary considerably from each other in the shape of the head and the form of the barbules on the lips. There are some of them which have only a single row of teeth, and these have usually a bony plate on the upper part of the head, and another on the neck between that one and the spine of the dorsal fin. Others have these two osseous pieces meeting each other, and forming one large shield, which extends nearly the whole way from the muzzle to the first dorsal fin; and there are others which have the head covered with the common integument the same as the rest of the body. In fact, the varieties in the form of the head, and in the armature, whether of teeth internally or of plates on the outside, are numerous. The diversities in these respects are so great, that the fishes are quite a study, although, in their appearance to outward observation, they all have a very strong common likeness.

Porcus. These have the teeth in the upper jaw composed of two parallel bands of thickly-set small teeth, one upon the intermaxillary bones, and the other on the vomer; the head is smooth, and the plate on the nape very small; some of them have the snout extended similar to that of the pike. There are several species of them found chiefly on the shores of Africa and its islands, and also in the larger rivers of that quarter of the world.

Synodontia. The teeth of this division are very peculiar and quite unique among toothed animals, much as these differ from each other. They have in the lower jaw a patch of teeth very much flattened laterally, but ending in crooked points, and standing upon flexible peduncles; they have a rough helmet on the head which extends in a bony plate as far as the base of the dorsal spine; that spine is also very strong and toothed. They are found in the larger rivers of Africa, but their flesh is of comparatively little value.

Argencios resemble the *Pimelodus*, only they are without the barbules at the mouth, though some of them have the maxillary bones continued in a sort of horny projections.

Doras have a row of osseous plates along the lateral line, each of which has an elevated keel terminating in a spine. Some of them are found on the coasts of North America, but not in high latitudes.

Heterobranchus. The fishes of this sub-genus are named from the very peculiar form of their gills. They have the gill-openings, and especially the gill-covers, smaller than in most of the family; and on the superior branch of the third and fourth bronchial arches there are tree-like appendages, which have some resemblance to the gills of tadpoles, and to those of the young sharks, while they continue enclosed in the egg. They have a rough and flat plate on the head, broader than in any other of the family, and having lateral plates which extend over the temples and the orbits of the eyes. They have a strong toothed spine in the pectoral, but none in the dorsal. There are a good many species of them, some with a second dorsal, and some without. They inhabit the rivers of Africa and Asia, and are especially abundant in those parts of the two quarters which lie most adjacent to each other. Generally speaking, their flesh is of inferior quality; but there is one, the *Sharmak*, or black fish, which is so abundant in Syria as to form a staple article in the food of the people.

Plotosus. The members of this sub-genus are distinguished from all the others by having two dorsal fins with rays to both. The second dorsal and the anal are both very long, and they meet at the extremity of the fish, forming a tail something like that of an eel. The lips are fleshy and prominent, their gape is armed in front with conical teeth, and behind these there are globular ones which, in the upper jaw, are situated upon the vomer. They have no naked plate on the head, but a covering of thick skin the same as on the body. The spines of the fins vary a good deal, some having them large and toothed, and others wholly concealed within the skin. They are mostly fishes of the oriental seas; and some, even of very small size, are very dangerous to handle, in consequence of the formidable character of these spines. One is mentioned, not above two inches in length, the wounds given by which are of so lacerated and ragged a character that, after handling it much, the hands cannot be moved for five or six days, and

every prick that it gives, though very minute, festers, and threatens gangrene. This is *P. ikapar*. It is deep black on the back, and white on the belly, with four yellow stripes extending from the muzzle to the tail.

Callichthys. These have the body completely covered on the sides by four rows of bony plates; but the muzzle and the under part are naked. The first dorsal has the spine short and weak, and the second dorsal has only one ray; but the spines in the pectorals are strong and rough. The opening of the mouth is narrow, and the teeth are very minute. The fishes sometimes crawl and climb out of the water in the same manner as eels.

The subgenera, of which we have now given a list, are those that make up Cuvier's genus *Silurus*; and, notwithstanding the extent to which it is subdivided, the subdivisions do not reach all the particulars of the characters of the species. Our information respecting them and the other genera that make up the family is, however, very imperfect, though the fishes are very numerous.

MALEPTERURUS. This genus gets its name from the only fin on the back being soft. There is no dorsal fin properly so called, but only a little adipose appendage near the tail. There is not a vestige of spine in the pectorals; nor any kind of armature upon any part of the body. The teeth are small, and cover a large crescent on the surface of the mouth.

There is only one known species of the genus, *M. electricus* (the *Silurus electricus* of Linnæus). It inhabits the rivers of the warmer parts of Africa, where it attains the length of from a foot to a foot and a half. It is a very slimy fish, and has the skin marked with very many black spots upon a white ground. The most remarkable character about it is an electric power, similar to that of the *Gymnotus* and the *Torpedo*; but, from the smaller size of the fish, not so formidable as it is in these.

The Arabs, who capture it in great numbers in the Nile, call it *Raad*, or the "thunderer;" but so far are they from having any superstitious dread of it, that they readily eat its flesh, and apply its fat for medicinal purposes, chiefly fumigations by burning it. The electric apparatus appears to be the same in this as in all the other electric fishes, namely, a series of tubes divided into numerous cells by cross partitions, and filled with a fluid. This is so perfectly analogous to a common galvanic apparatus, that there seems every reason to believe that, in the one as in the other, the energy is obtained by a decomposition; but whether the decomposition of water we are unable to say. As is the case in the others, the electric apparatus is very amply furnished with nerves.

ASPREDO. The characters of this genus are very well defined. Their head is very short, and the fore part of the body very broad, owing to the large size of the shoulder-bones; the tail is also very long; the eyes are small, and have an upward aspect. Their most remarkable character, however, and one which distinguishes them from all the other bony fishes, is the immobility of the gill-lid. The opening of the gills by which the water is discharged is a simple slit, at the back part of the side of the head. The species are not numerous.

LOBICARIA. This genus are named from the bony plates that cover the whole body and head; and they are distinguished from all the other armed *Siluridae*, by the mouth opening under the muzzle. Among

the other members of the family, *Synodontis* is the one which has the mouth most nearly resembling that of this one, but there are many differences. The intermaxillary bones are small, and suspended under the muzzle; and the mandibularies are transverse, not united, and furnished with long and slender teeth, crooked at the points. A large circular veil of membrane surrounds the mouth; and the bones of the pharynx are covered with teeth like a pavement. The gill-lids properly so called are as immovable as they are in the genus *Aspredo*; but there is a small moveable plate jointed to the side of each, which appears to perform the function of the whole. They have four rays in the gill-membrane. The first rays of the dorsal, of the pectorals, and even of the ventrals, are furnished with strong spines. They have no caecal appendages to the intestines; and it does not appear that they have any air-bladder, though every other genus in the family is provided with one. In consequence of considerable differences in the characters of the known species of the genus, it has been divided into two subgenera.

Loricaria properly so called. The fishes of this subgenus have only one dorsal fin, situated far forward on the body; the membranous veil or appendage to the lips is furnished with barbules, and in some cases it is roughened all over with papillæ; and the under part of the body is covered with osseous plates, as well as the upper and lateral parts.

One of the most characteristic species of this subgenus is *L. cataphracta* of Linnæus. It is an inhabitant of the fresh waters of South America. It has the caudal fin much forked, and the first ray of the upper lobe very long, often longer than the whole body of the fish; but this is apt to be broken in dried specimens, and thus the drawings taken from them give a very imperfect idea of the true character of the fish.

Hypostomus. These get the name of "under mouth" to distinguish them from the preceding subgenus. They have a second dorsal fin of small size, and with only a single ray. Their labial membrane is beset with papillæ; but it has no barbules, except a small one at each side of the upper jaw. The belly is also without osseous plates. Their intestinal canal is much convoluted, and at least five times the length of the body. Like the preceding subgenus, they are known only as inhabitants of the fresh waters of South America.

Such is a very brief outline of the family of the *Siluridae*, which are, next after the salmon family, perhaps the most interesting of the fresh water fishes; and they far exceed them in size. They are among fishes what the hippopotami are among the river mammalia; and both races are most abundant in the same latitudes, and also in the very same rivers. They, however, lie too far from the scene of accurate observation for our being able to say much of their relations to the rest of nature, or the part which they more immediately perform in the system; but they are so numerous, so varied, and some of them of such size, that their function must be important.

SIMARUBACEÆ. A small natural order containing three genera and five species. The genera are, *Simaruba*, *Semaba*, and *Quassia*. They are trees or shrubs with an excessively bitter bark, a milky juice, and pinnated leaves. The *Simaruba officinalis* is well known as the most pure and intense bitter hitherto discovered. The same quality exists, in a milder degree, in the rest of the order. The flowers

are decandrous, with one pistil; the carpels are two-valved, and one-seeded. In our stoves they thrive in loam and heath mould, and are propagated by cuttings.

SIMPLEGAS. A fossil mollusc allied to the *Ammonites*, from which it is distinguished by the septa being plain, and not sinuous.

SIMULIUM (Latreille). A genus of small dipterous insects belonging to the family *Typulidæ*, having the eyes large and internally notched, the ocelli obsolete, the antennæ short and eleven-jointed, and the proboscis pointed and perpendicular. These are minute insects like midges, which abound to a very great degree in damp situations, where they attack the inhabitants in the same manner as the real gnats (*Culicidæ*); indeed in South America it would appear from the recent work of Messrs. Pohl and Kollar, that the same name mosquito is given to both the *Culex* and the *Simulium*. In some of the Northern parts of Europe their irritating powers are so great, that the inhabitants are compelled to cover themselves with a coating of grease. The type of the genus is the *Simulium reptans*, Latreille. In North America they are distinguished from the mosquito under the name of the black fly.

SINAPIS (Tournefort). A genus of hardy annual herbs, several of which are cultivated for their pungent seeds, of which the common condiment mustard is manufactured. The flowers are tetrandrous, and belong to *Cruciferae*.

SINNINGIA (Nees). A genus of South American under-shrubs belonging to the natural order *Gesneriæ*. This is a succulent genus, and succeeds in any rich dry soil; and young cuttings planted in the same soon make roots.

SINODENDRON (Fabricius). A genus of coleopterous insects, belonging to the family *Lucanidæ*, distinguished by having the body elongate and cylindric; the head of the male armed with an erect horn; the antennæ elbowed, ten-jointed, the first joint being very long, and the three terminal joints forming a deeply serrated club; the legs short, with the tibiæ spined. The genus comprises a single British and several exotic species, the former being the *Scarabæus cylindricus* of Linnæus. This species is found in Normandy in the rotten trunks of apple-trees, and in Flanders in decayed beech-trees. In England it appears to be more frequent in the ash and willow, as we learn from Stephen's British Entomology, and the following observations of the Rev. W. T. Bree, published in the Gardeners' Magazine:—A living ash-tree, standing on his premises, was blown down on the 3rd December, 1832. Its trunk, for about eighteen feet up from the part that had been level with the ground, was hollow and decayed at the centre, and afforded some twenty or thirty good barrow-loads of rotten wood. Throughout this carious portion of the tree there occurred numerous individuals, both in the larva and imago state, of the *Dorcus parallelipedus* (another species of the *Lucanidæ*), and of its usual associate, the *Sinodendron cylindricum*, but not a single pupa was discovered; they had perforated it in all directions. Many were found pursuing their occupations in the decayed timber at the distance of eighteen feet from the ground, to which height they must have worked their way from the bottom. He was satisfied that they did not commit any injury on the living or sound wood, attacking such only as they found far gone in

a state of decay. This insect is of a black colour, and varies in length from one half to three-fourths of an inch.

SIPHONARIA (Lamarck). A patelloid shell, elliptical, the summit well marked, a little on the left, posteriorly, a canal or gutter on the right side, the muscular impression in the form of a horse-shoe, the right lobe divided in two by the canal.

SIPHONIA (Richard). The *S. Cahuchu* is the Indian-rubber tree, called *Jatropha elastica* by Linnaeus. The flowers are monœcious, and belong to *Euphorbiaceæ*:—cuttings.

SIPHONOBANCHIATA constitute the first order of the second class *Paracephalophora* in De Blainville's Malacology. The leading characters of these molluscs is their organs of respiration being constantly formed by one or two pectiniform branchia, obliquely situated on the anterior part of the back, and contained in a cavity whose upper coating is provided with a tubular canal more or less elongated, and attached to the columella. The first family of the order is the *Siphonostomata* genus *Murex* of Linnaeus, and includes the genera *Murex*, *Pleurotoma*, *Rostellaria*, *Fusus*, *Pyrula*, *Fasciolaria*, *Turbinella*, *Columbella*, *Triton*, *Ranella*. The second family the *Entomostomata*, is Linnaeus' genus *Buccinum*; it includes the *Cerithium*, *Melanopsis*, *Planaria*. *Subula* *Terebra*, *Eburna*, *Buccinum*, *Harpa*, *Dolium*, *Cassidaria*, *Cassia*, *Ricinula*, *Cancellaria*, *Purpura*, *Concholepas*. The third family, *Angustostomata*, includes the *Strombus*, *Conus*, *Terebellum*, *Oliva*, *Ancillaria*, *Matra*, *Voluta*, *Marginella*, *Peribolus*, *Cypræa*, *Ovula*.

SIREN. A genus of *Batrachian* reptile, and the last both of the order and the class in the arrangement of the animal kingdom by Cuvier. To this place in the system it is unquestionably entitled, as the animals composing it partake of the characters, and even of the forms, both of reptile and of fish, though that of reptile, on the whole, predominates.

Animals of this genus are the only known ones that are true *Amphibia*, furnished with both lungs and gills, either of which they can use at pleasure. The characters are: the body elongated, and nearly in the form of that of an eel; three tufts of gills; no hind feet, and not the least vestige of a pelvis; the vertebra of the spine very numerous, and articulated something in the manner of those of a fish, that is, with the proximate ends concave, and united by cartilage which forms the joint, so that there is no motion of bone upon bone, and there are only eight ribs upon each side. The body of the siren may thus be regarded as consisting of only a thorax and a tail; the former being that of a reptile, and, as such, furnished with feet; and the latter that of a fish, producing fins only. The head is flattened, the muzzle blunt, the opening of the mouth small, the eye very small, and the ear hidden in the skin; the lower jaw is furnished with teeth all round, but the upper jaw has none, though there are several rows upon two plates, one on each side of the palate.

There have been many disputes respecting the siren, and not a few have been disposed to regard it as the tadpole of the salamander. But Cuvier has demonstrated that the gills are part of the permanent structure of the animal, and not temporary organs, like the gills of tadpoles, to fall off or be absorbed when the animal comes to maturity; and he remarks that some of the sirens are much larger than any salamander even in the full-grown state. This struc-

tural demonstration is completely borne out by the physiological fact that the siren breeds while the gills on it are perfect, and in no one instance has one individual been seen in which there was the slightest symptom of decay in the gills. The capacity of breeding is the most complete evidence that we can have of a perfect animal; and in the whole of the animals that undergo transformations, whether they pass from the water to the air as their element or not, there is not one which has the faculty of breeding until it has gone through its last and completing change. From this it is obvious that, physiologically considered, the siren is a complete and perfect animal; and what more than this could it become by any subsequent transformation that it could possibly undergo?

That both systems of respiratory organs are perfect in the siren has been proved by observation. The gills are as complete in all their parts as if the animal were a fish, and never could breathe but through the medium of water; and the lungs are also perfect, with an abundant ramification of blood-vessels. Either system can therefore be used as occasion requires, and this is not the case with any other known species of vertebrated animals. A siren must not, therefore, be confounded with any kind of tadpole; for, whatever may be the external appearance of these, they never have the two modes of respiration perfect at the same time. That the tadpole must pass from the state of a breather by gills to that of a breather by lungs, is quite evident; but the transition is one of those momentary mysteries that we can never hope to understand, but must satisfy ourselves with a simple statement of the fact.

Among vertebrated animals the sirens thus stand alone as the most peculiar of the whole in their vital system; and from this we may be prepared to find them inhabiting a singular part of the country, or rather of the world. Such is the fact. They are found chiefly in the warmer and more southerly parts of the United States, where much of the surface is covered with marshes, but marshes which are in a great measure seasonal, covered with water at one period of the year, and as dry as dust at another. While they are humid the sirens have the habit of fishes, and when they are dry these animals breathe air; and thus they can pass the whole year in situations where no other animal can. They live upon worms and small mollusca, larvæ, and other minute animal matters. There are three species, but there is not much of interest in them beyond that double power of breathing to which allusion has been made; and therefore a very brief notice of them will suffice for our purpose.

THE LARGER SIREN (*S. lacertina*). The name *lacertina* is inaccurate, as it implies that the animal bears a resemblance to the saurian reptiles, when in reality it does not; and there is really nothing lizard-like in its appearance. It grows to the length of three feet, is generally of a black colour, has four toes on each of the fore feet, and the tail compressed, with the fin blunt. When in the water it swims by lateral flexure of the tail, in the manner of a fish, and not by vertical motions, as in the air-breathing animals that find their food in the water. It is very common in the marshy parts of Carolina, especially the rich grounds that are cultivated for rice, and which are of course laid under water at certain periods of the year. Such places abound much in

worms, and these constitute the chief food of the siren. It is a dull and sluggish animal, not very agreeable to the sight, and crawls and pokes about in the sludge, which appears to be much better suited to it than either the dry land or the free water. Here we find one of those remarkable coincidences of animal and place which are so demonstrative of design in the whole system of nature. The proper locality of the siren is neither water nor land, but both by turns, and the animal is organised for both of them as they may happen to present themselves in turn.

The other two known species are,

THE INTERMEDIATE SIREN, of the same colour and form as the above, but with the gill-tufts less developed, and the whole length of the animal only about a foot; and

THE STRIPED SIREN, which has two lines of yellow along the whole of each side, the gill-tufts still less developed, only three toes upon each of the feet, and not above nine inches in length. These are perfect animals as well as the larger one, and their gills are a perfect breathing apparatus, though less perfect than in the large one. It is probable that there are, in the obscure haunts of these animals, many species yet to be discovered.

SIRICIDÆ (Leach). A family of hymenopterous insects, belonging to the section *Terebrantia securifera*, and having the abdomen united to the thorax by its whole breadth; the mandibles short and thick; the labrum entire; the ovipositor of the females generally exerted, composed of two external sheaths, inclosing a horny, elongated, and pointed dart; the antennæ are filiform or setaceous, and composed of from ten to twenty-five joints; the body generally cylindrical. The family comprises the genus *Sirex* of Linnæus (*Urocerus* Geoffroy), from which the genus *Tremex* of Jurine has been separated, and *Oxyssus* (which see). The typical genus *Sirex* has the antennæ frontal, from thirteen to twenty-five-jointed, the maxillary palpi very minute, the wings with three sub-marginal cells, and the abdomen produced into an acute point.

These insects, which are of considerable size in general, inhabit the pine and fir forests of cold and mountainous countries, to which they are occasionally injurious, the females depositing their eggs, by the assistance of their long ovipositor, in the substance of the wood, and the larvæ eating into the solid substance of the trees, forming cylindrical burrows.

In certain years these insects appear in great numbers, so as to occasion alarm amongst the ignorant and superstitious. During flight they make a loud buzzing noise like humble bees. It is not an uncommon circumstance for them to make their appearance in the winged state in newly-built houses, having been brought in the deals of which the floors, &c., have been made, in too new a state, whilst they were still larvæ or pupæ, occasioning alarm from their slight resemblance to hornets. The larvæ have six very short legs, and the extremity of the body is armed with an acute horny point; it forms a cocoon in its burrow, in which it undergoes its metamorphoses. The Count Saint Fargeau, in the *Encyclopédie Methodique*, and his recent work on the *Hymenoptera* (Suites à Buffon), has considered this tribe of insects as parasites, but he is certainly mistaken, as we have abundant proof to the contrary. The species are not numerous, the type being the

Sirex gigas of Linnaeus, the female of which is more than an inch long, black, with the second and three terminal joints of the abdomen orange-coloured. The male has the abdomen of a darker orange, with the extremity black. It is very rare in this country, a more abundant species being the *Sirex juvenicus*.

SISON (Linnaeus). A genus of annual and perennial herbs, natives of Europe. It belongs to *Umbelliferae*, and in English lists is called honeywort.

SISYPHUS (Latreille). A genus of coleopterous insects, belonging to the subsection *Lamellicornes*, and family *Scarabaeidae*, having the four hind legs very long; the elytra have not a notch at the shoulders, and the antennae are eight-jointed; the body sub-convex. This is a curious genus of dung-rolling beetles, nearly allied to, and having similar habits with, the genus *Gymnopleurus*, which see. The genus are chiefly confined to the arid parts of the south of Europe and Africa. The most remarkable species is figured in our plate of beetles, *Sisyphus spinipes* of Gory (Monograph. Sisyph., p. 8). It is of black colour, slightly pilose, with the front of the head notched, the middle thighs with one tooth, and the posterior with four. It is from the Cape of Good Hope.

SISYRINCHIUM (Linnaeus). A genus of ornamental herbs, natives of various parts of America. The flowers are tetrandrous, and the genus ranks among the *Iridaceae*. Some of the species are nearly hardy, but they are generally potted in light soil, and kept in frames.

SIUM (Linnaeus). A genus of herbs, mostly aquatics, and commonly called the water-parnep. The genus belongs to *Umbelliferae*, and one has been introduced into the kitchen garden, and cultivated for its roots, under the name of Skirret.

SLATE, or **SHALE**, as it is frequently called, is a very abundant and useful mineral. The slate district of England is of considerable extent. In Cornwall it is seen immediately incumbent upon granite, and the slaty districts form very beautiful scenery upon many parts of our coast. But this mineral appears on the large scale, and in peculiar grandeur, in the mountain-chain which includes Snowdon, Plynlimmon, and Cader Idris. These mountains have an enormous elevation, their summits are jagged and irregular, their declivities steep and barren, and the neighbouring passes and valleys of slate formation are of the most romantic character. London is chiefly supplied from Caernarvonshire and Westmoreland. Argyle and Dumbartonshires also produce vast quantities.

SLIPPER-WORT is the *Calceolaria pinnata* of Linnaeus, a fine genus of South American annuals, perennials, and undershrubs, belonging to *Scrophularineae*. The species are highly ornamental, and the varieties numerous. Cuttings, seeds.

SLOANEA (Linnaeus). A genus of trees and shrubs, natives of South America, and named in honour of Sir Hans Sloane, P.R.S., and belonging to *Tiliaceae*. One species is a timber tree, but they may be kept and propagated in our stoves.

SMERINTHUS (Latreille). A genus of lepidopterous insects, belonging to the family *Sphingidae*, having the antennae somewhat prismatic, and serrated with a terminal brush of hairs. The spiral tongue is almost obsolete; the palpi compressed, covered very closely with scales; the wings, with the external margins, notched and angular; the caterpillars are covered with very minute tubercles or warts; the

terminal segment armed with a conical horn, and the head somewhat triangular; they feed chiefly on the leaves of trees; the chrysalis is slightly rugose, and pointed at the extremity of the body, and is subterranean. These are dull heavy-bodied hawk-moths, which seldom make much use of their wings, thus differing from the generality of the family. This peculiarity is entirely dependent upon the obsolete structure of the spiral tongue, which (instead of being of very great length, as in the true *Sphinges*, which derive their name, hawk-moths, from their habit of hovering over flowers, and extracting their sweets by means of their proboscis) is in the *Smerinthus* so extremely short, as to be useless to the insects. There are three British species, the eyed hawk moth (*Sm. occellatus*), the poplar hawk-moth (*Sm. populi*), and the lime hawk-moth (*Sm. tiliae*). They are all sufficiently common, and are handsome insects of comparatively large size.

SMILACEÆ. A natural order comprising twelve genera, and above one hundred species. This order, including *Smilax*, *Ruscus*, *Trillium*, *Paris*, &c., are, on one hand, associated with the *Dioscoreaceae* by their broad leaves, and on the other with the *Asphodelaceae*, by their generally perigynous anthers and superior three-celled ovary. The characters, however, which associate them with either distinguish them from each other. Thus the superior ovary takes them from *Dioscoreaceae*, and the broad leaves from *Asphodelaceae*; and such genera as have the foliage not reticulated are known by the triple style and membranous testa, which latter is characteristic of all the *Smilaceae*. Various species of the order are esteemed for their alterative properties; they are tonic, diuretic, and demulcent. *Smilax aspera* is by some preferred to the drug sarsaparilla; which drug is the produce of the *S. sarza*. The genera are mostly hardy, and increased by division.

SMYNTHURUS. See **PODURIDÆ**.

SMYRNIUM (Gartner). A genus of biennial and perennial herbs, natives of cold countries. The flowers are pentandrous, and the genus belongs to *Umbelliferae*. One of the species was formerly a kitchen garden vegetable, and cultivated under the name of Alisanders, and used in the stead of celery, which last has superseded the former.

SNIPE (*Scolopax*). A genus of the longirostral family of Echassiers in Cuvier's arrangement, and the typical one of the whole family, as one may infer from the name *Becasse*, or "beaky," given to it by the French. The characters of the genus, as taken generally to include the subgenera, which do not, however, comprise nearly all the birds that were included in the Linnaean genus *Scolopax*, may be stated as follows: the bill long, straight, enlarged at the tip, with the upper mandible larger than the under one, and the enlarged part of it bending over the tip of the other like a hook. The mandibles forwarded for half their length, and the lower one canaliculated and truncated at the tip. The nostrils basal and lateral, cleft longitudinally, and covered by membrane; the feet of mean length and slender, and, in the true snipe, having the tibiae feathered down to the tarsal joint, and three toes to the front and one to the rear; the wings are of mean length, the second quill the largest in the wing, but the first one nearly equal to it; the eyes are placed so far backwards in the head that the birds can command the whole horizon without turning, and it is in this that their

safety lies, for they are without any weapons of defence; they are feeders upon small animals, and their flesh is much esteemed.

Snipes are birds that make very little noise in the world, excepting the cry of the male in the pairing time; and they spend the greater part of the day in concealment among the herbage. They are found in marshy places, and generally where there is an abundance of tall aquatic herbage to conceal both themselves and their nests.

The bill of the snipe is a very curious instrument, and seems to be possessed of very high powers of sensation, both of smell and of taste. The animals bore into the soft sludgy ground for no inconsiderable portion of their food, and as they bore down directly upon it, and do not dabble along, and sift the sludge for it, as is done by the flat-billed birds, they must scent it from the surface, or, at all events, before they reach the depth at which it is situated. Dabbling would not answer in the places where they find their subsistence, as it can be performed only where there is water to wash away the substances which are not edible. The dabbling birds are accordingly all web-footed, have their bodies boat-shaped, and are otherwise adapted for swimming while they feed at the bottom of the shallow water, or if their habit be to get upon deeper water they can dive; but the snipes always have the feet on the ground while they feed, and though they are birds of moist places they are not formed for swimming or for diving. The working of such a bill as theirs would, in part, be impossible in the case of a bird floating on the water; the form of the head is peculiar, and the peculiarity is of course adapted to the action of the bill. The head is square in the profile, and extends over the base of the bill in all directions, so that in whatever way the bill may work in the ground, the weight of the head is ready to assist it in its lateral twistings, as the animal bores into the sludge. The feet of the snipes are much better adapted for walking upon the surface of soft mud than an elastic vegetation, as they are without the long hind toe, which is so essential in the latter, they are in fact birds well adapted to those pastures; and, when on a pasture properly adapted to them, they have no great deal of labour to perform in the finding of their food. The nature of the places to which they are best adapted renders them migratory birds in most parts of the world, as they are equally liable to be frozen out by the cold and parched out by the drought; accordingly they migrate either from country to country or from one part of the same country to another, at the opposite seasons of the year. We need hardly mention, that when they migrate, in latitude, their migrations are southward from the winter cold, and northward from the summer heat; and that if the country be so diversified with plain and mountain as that they can find the seasonal range adequate to their wants, they merely shift from mountain bog to lowland marsh in the winter, and back again in the summer; by this means they enjoy, even in the countries where they are resident the whole year round, a much greater uniformity of climate than most other birds, except those that live actually upon the waters. They are, however, so close in their cover during the day that they are seldom seen, and many of them may be found in places where they have never been suspected of visiting.

The species are rather numerous, and they are distributed over very many countries; but as their

manners differ little, it will be sufficient to notice those that are found constantly or occasionally in the British islands, and merely to name some of the others.

THE COMMON SNIFE (*S. gallinago*). This may be regarded as the typical bird with us, though the woodcock, which is a larger bird, and one in more esteem with epicures, is the *Becasse* of the French, and this one is the *Becassine*. The common snipe is about nine inches long in the head and body, and the bill is about three inches. The weight, when full-grown, is about a quarter of a pound; the bill is dull reddish at the base, yellowish in the middle of its length, and brownish at the tip; from its soft consistency, as containing much more living substance than a hard bill, it becomes shrivelled and loses its colour after the bird is dead; the colours are much broken and mottled, and thus not easily described; the top of the head is dark brown, marked with three longitudinal lines of cream colour, a bright one along the middle, and a more obscure one on each side over the eye; from the gape over the eye and down the side of the neck there is a brown streak, which is broken into a row of spots after it passes the eye; the back is black with glosses and reflections of green and brown; and the feathers on the shoulders have the one striped longitudinally, and the other barred across with yellow; the wings are dusky with some brown bars, and white tips to the quills; the tail-coverts are reddish brown; and the feathers which appear only a little way beyond the coverts, have black bars; the chin, throat, and fore neck are whitish with irregular markings of brown, and the rest of the under parts are white.

In winter they are very common in the fens and marshes, and by the tangled banks of streams in the low and warm parts, and not one remains in the mountain bogs, and it is probable that a considerable number come from countries further to the north, especially when the winter in these is early and severe. In summer the departure, or, at all events, the disappearance, from the low grounds is quite as complete; and, indeed, unless when one comes upon it accidentally, a snipe is very rarely to be seen in summer, even in those places where the cry of the male in the spring shows that they are in the country. On their migrations their flight is always lofty; and, though they are occasionally heard on their march, they are rarely if ever seen.

The Snipe.

The cry of the male begins in March or April, according to the place and season, and he continues to call until a partner answers; but after this he only treats her with a nocturnal song. The sound is shrill but harsh and trilling, and it has been alleged that the bird can trill upon the air with its wings, as is done by many of the insect tribes; but this is by no means probable, as no feathered wing is competent to the performance of such an office. The nest is always in close concealment among the thickest of the rushes or other herbage, and rudely constructed of vegetable

fibres. The eggs are four in number, of a pale greenish grey with brown spots, and they are placed in a cross with the four small ends at the centre. The young, as is the habit in all ground birds, come out of the shell covered with down, but with their feet so well developed, that they are very speedily able to find their own food; but they do not come to full maturity till the following spring.

At all times they lie close in the bushes and other herbage, and cannot be raised to the wing without much difficulty, they are also very short and "twitchy" in their flight; and thus snipe-shooting requires some training both in the dog and the sportsman. Birds of prey also find the snipes laborious game. In the first place they have to beat a long time before they can "flush" a snipe, that is, make it take to the wing; and then if it gets the start but a little way, it wheels and doubles so often and so rapidly, that if the hawk is not altogether thrown out, the chase is often a very protracted one.

THE WOODCOCK (*S. rusticola*). The woodcock is a much larger and more celebrated bird than the snipe. The total length of it is about one foot three, and the weight from three-quarters of a pound to nearly a pound; the bill is considerably longer than in the snipe, but formed in much the same manner; the forehead is ash-colour, and all the rest of the upper part barred with black and grey; the under parts are yellowish, with longitudinal dusky streaks; the tail consists of twelve black feathers with rust-coloured margins to their outer webs, and ash-coloured tips; their under surface is whitish. There are, however, very great varieties both in the size and colour of these birds; and, according to some of the authorities, the female bird is larger than the male.

The woodcock is in the great majority of its numbers, a bird of passage in Britain, and it was long a question whether any remain to breed. The point has been settled by the actual discovery of nests and broods both in England and Scotland. The eggs and young have not been found in any considerable number, but they have been met with at points along almost the whole length of the country.

They are birds of wild marshy copes, where they can find food in the sludge by the sides of the pools and runs of water. Solitude, shelter, and humidity are the three essentials of the woodcock; and it requires them all jointly. Hence, as cultivation changes the character of a country, these birds shift. Drainage, cultivation, and increased population drive them from the richer parts of the country, however well these may be wooded. On the other hand, the uncultivated moors, however humid they may be, are as ill-adapted for them; and thus when such places are planted with copes in lonely spots near the water, the woodcocks will come, and if the places continue humid enough during the summer, they will remain and breed. The first of these changes has gone far to banish them from some parts of Britain even as visitants, and the other has made them partially resident, and plenty as visitors in places where none formerly existed. In Scotland this has been especially the case on the southern slopes of the Grampians towards Strathmore, and in Ross-shire about the head of the frith of Cromarty; and no doubt there have been instances as remarkable in other places, both in the north and the south of Britain, and especially where plantations have been formed in Ireland.

The grand resort of the woodcocks in summer is,

however, understood to be the marshy woods to the north of the Baltic, and the farther north, so that the place is wooded, the better, as the insect food for the birds is not only more numerous, but the sludge of the marshes is more exclusively the *nidus* of the larvæ. Hence, to make sure that woodcocks shall breed in any place, the best way is to make it "as like Lapland" as possible. The birds remain in concealment in the woods during the day, and come out only when the evening begins to get damp, at which time they utter their peculiar cry which resembles that of the snipe, but is less harsh and shrill. They are more social birds among each other than the snipes, and generally come to the feeding grounds, and also quit them in little parties, and they follow the same paths. Their flight on these occasions is always low, as if they sought cover even when they are flying. From this habit they are easily taken by means of nets. Springes and nooses were also much in use in former times, when there were far more neglected pools and marshy places in England than there are now; and the ease and certainty of this mode of capture are alluded to by Shakspeare, when he mentions "Springes to catch woodcocks," a kind of sport- ing which the bard himself had no doubt often tried.

Woodcocks are very expert in finding out where there are worms and other little animals in the ground, and they are just as dexterous at drawing them out. The first discovery must be made by the scent, because there is no other sense which the bird can exercise; and then, the worms are so quick in perceiving any agitation of the earth, that the securing of them by means of a bill boring and poking in the ground, is a very curious matter.

The nests of these birds are usually placed in the thick underwood at the roots of the trees, or in bushes, and they are formed of dry vegetable matters, such as moss and leaves, and withered stalks; the eggs are four in number, larger than those of the common pigeon, of a dull yellowish white colour in the ground, and spotted with ash-colour and reddish brown most abundantly at the larger ends. Such nests as have been met with in Britain have generally had eggs in them in June; and it is highly probable that, in all countries in which they breed, the longest days are their favourite season. The long twilight of such times is advantageous to them; and in those latitudes where they breed most abundantly there is twilight all the night through for a considerable time, and for some time sunshine. There are frequent fogs in such places, and while they are on the surface is the feeding-time of the woodcocks. The quantity of food, especially of earth-worms, which the woodcock consumes, is perfectly wonderful; and those who speculate about the matter come to the conclusion that it would be hard labour for a man to find, in this way, the food of three woodcocks. This even exceeds the labour which is said (satirically most likely) to have once fallen on the ladies of honour and the courtiers of a certain royal establishment, in consequence of a gift of lizards having been made to a queen. These lizards would eat nothing but flies; and the attendants at the royal palace were so completely worn out with fly-hunting, that it was at last resolved to call in the aid of the household troops; but, fortunately, a severe frost put a period to the life of the lizards, and thus the fly-catching was at an end, much to the joy of the exhausted courtiers.

It is in the autumn and winter that the woodcocks

feed chiefly upon earth-worms, for at those times of the year the number of other living creatures in the sludge and mud is much less than during the warm time of the year. In all probability it is from being composed of earth-worms that the "trail," or contents of the stomach of the woodcock, is reckoned so very savoury a mess by the epicures; for those gut-birds which feed nearer the water, and consequently more upon insects, larvæ, and mollusca, are said to have the trail far inferior. This is a matter, however, which can hardly be said to belong to the natural history of the birds. We may farther mention, as indicative of the fact that the woodcock is not an inhabitant so near the water as the common snipe, that it has the tibix feathered down more closely to the tarsal joints.

THE GREAT SNIPES (*S. major*) is not nearly so large as the woodcock, not being above an inch longer than the common snipe. It has the head of a deep black colour, with three light stripes like those on the common one; the upper parts are black, and pretty clear red, variously mottled together; and the under parts are reddish white, with some longitudinal dusky streaks on the belly and flanks; the shaft of the first quill of the wing is white. This is a European bird, breeding in the north, and removing southward in the winter; but it belongs to the east of the country as divided by the central heights, and thus the grand line of its migration is that of the Black Sea and the Archipelago, and not of the shores of the Atlantic. It does come a considerable way to the westward, and sometimes, but not very frequently, straggles into Britain, but on its southward journey, and not its northward one. It is a much heavier bird than the common snipe in proportion to its lineal dimensions, and therefore it is not so well suited for very long migrations. The marshes of the northern parts of Europe, to the east of the Baltic, are said to be the places to which the greater number resort in the nesting time; and the economy of their nests is said to be very much the same as that of the common snipe in our own marshes. It is possible, however, and even probable, that it may be only a climatal variety of the common snipe, for we believe that it is not unusual for birds to be larger in size, and more intense in colour, in the east of Europe than in the west. Snipes are, altogether, rather puzzling birds, for they are so much concealed, that they may be in many places where we never suppose them to be; and there may also be many species of them in Europe, and even in Britain, which have not yet been noticed.

SABINE'S SNIPES (*S. Sabini*). This is a species of which we have the knowledge only of late years; and thus it is one of those that show us how careful we ought to be of coming to hasty conclusions in the case of birds of such hiding habits as the snipes. This is a smaller bird than the common snipe, but with the bill very considerably longer in proportion. The general colour is brownish black, relieved by chestnut and rust-colour on the margins of the feathers, which give it a very rich, and, at the same time, a very pleasing mottled appearance. It is a small species, but a very pretty one, and has in some particulars much more resemblance to the jack snipe than to the common snipe. For instance, the feathers on the tail of this one are twelve in number, the same as in the jack snipe, while the common snipe has fourteen, and the great snipe sixteen. This comparatively limited number of feathers in the tail points out that

the bird is one of hiding habits, and fond of concealing itself in the tall vegetation; for, almost without a single exception, birds which have broad tails inhabit open places. Specimens of this snipe have been met with in different parts of both Britain and Ireland at such times as to show that it could hardly have been a straggler from any migration; and therefore, if it is not a mere variety of the jack snipe, which is not impossible, the probability is, that it is a resident species breeding in some parts of the British islands.

THE JACK SNIPES (*S. gallinula*) is a very pretty little bird, only about half the volume of the common snipe, that is, not more than two ounces in weight. The bill is about two inches in length, and of a lead-colour in the general part of its length; but the tip is black, and the culmen of the upper mandible is horn colour; the irides are dusky black; the upper part of the head is black, with very faint margins of rust colour to the feathers; there is no line on the middle, but a yellowish streak on each side, with a dusky one below it, and another pale coloured one over the eye; there is also a dark line from the angle of the gape to the eye; the back, the scapular feathers, and the rump, are of rich green and purple, varying in tint as the light falls differently upon it, and the scapular feathers have buff margins, forming two very conspicuous lines on the shoulders of the bird, which run all the way from thence to the tail; the neck is marked with rusty brown and dusky, with some cloudings of ash colour on the upper part; the coverts of the wings are dusky, marked with ash colour and brown, and the quills are dusky; the tail is wedge-shaped, consisting of twelve feathers of a dusky colour, but more or less clouded with rusty red; the under parts are nearly white; and the legs are of a greenish colour.

There are few British birds concerning which there have been more mistakes than the jack snipe. As is the case with very many birds which, on account of their dispersion over the wild parts of the country, and their concealed habits during the breeding season, the common describers of birds cannot easily see at those times; the jack snipe has been packed off "bag and baggage" to breed in the polar regions, without surference to remain in any decently southward climate during the summer. But it is one thing to write a bird into the polar regions, and another to send it personally there; and there is no truth in description, if the writer of this article has not seen the jack snipe full fifty times and more, in the reedy pools upon the first uplands of Britain many times in the course of the summer; and he once caught it with hook and worm by the tangled bank of a wild stream, at the head of a mill-pond, when angling for quite another sort of game. The smallness of the bird, the lightness of its motions, and the two lateral stripes on the back from the shoulders to the rump, are not to be mistaken; and thus the only sound conclusion is, that, though this bird unquestionably leaves the places near the sea, and moves into the uplands in the summer, it breeds, and that in no stinted numbers, within the country. The fact is, that though the authorities, who have been generally men of the south, or of the sea-coast, where the birds do not breed, have represented the jack snipe as a comparatively rare species, it is perhaps one of the most plentiful of the whole genus, and one of the most generally distributed over different countries.

In Britain the jack snipe takes its departure from the marshes in the low and warm parts of the country, near the shores, as early as March, or even as February, according to the season. Now, even the latest of those times is not exactly the one at which a bird should set out from Britain to the polar regions, because there is little for a bird there until June, or May at the earliest. But the objection does not hold in the case of a bird moving by stage and stage from the margins of the sea to the marshy moors in such a country as Britain. There is another consideration: if the jack snipes of this country went off to the far north, we might expect them in considerable numbers in the Orkney and Shetland isles; but this is not the case. They are mentioned as occurring in some of the Orkneys, but they are described as being rather rare birds, much more so than in places farther to the south. The case would be very different if the birds, *en masse*, passed over the latitude of these islands, for migratory birds, as might be expected, never omit halting to rest and feed on any islands that may be in the line of their march.

The grand foundation of the difficulty appears to lie in the retiring habits of these snipes. In the district where, as we have mentioned, we saw them so often, we never by any chance saw one on the wing, or in any other way than by the direct invasion of the tangled pools in which they find convenient nesting places, and an abundant supply of food; and there is no doubt that any one, who chances to look for them in such places during the breeding season, will find them in abundance, though not congregated in the same place; for under all circumstances, and at all seasons of the year, they are solitary and retiring birds, not to be "flushed," or raised from their hiding places, without very considerable effort, and also knowledge of the ground. The places in which these snipes are found, in the breeding season, are of the most difficult character; that is, where no predatory quadruped can go, and where the ordinary birds of prey cannot easily find them, in consequence of the closeness of the cover. But these, and many of the other ground birds which breed in the marshes, find destroyers of their eggs that would not be suspected, in those gulls which breed in the same places. The place of which the gulls take possession is safe in this way; for the gulls inhabit closely in large societies, and no other bird will or can breed in the same locality. But they prow about in the neighbourhood, and are terrible robbers of nests.

The Jack-snipe is one of the prettiest of all our marsh birds; and when it whisks about among the tall grass and *equisetums*, the fine gloss on the back, and the two lateral stripes give it a most lively appearance. The nest is very difficult to find, as it is always so placed as that the bird can glide to some distance from it before it disturbs the grass. To seek for either nest or bird is a hopeless matter; and at the pools of which they inhabit the margins, one must take the chance of finding them without an actual beating of the course.

Though these birds resort to the pools on the elevated moors, they are not found in the higher mountain bogs; and if there is cover enough they keep their place, though the labours of the agriculturist and the grazier are going on around them. But a country favourable for them is most unfavourable for agriculture, as the tangled bogs, which they frequent,

occasion blights in the latter part of the spring and early in the autumn; and thus where snipes nestle, unless in places wholly abandoned to wild nature, there is a strong admonition to man to commence draining; and the drainage of those little bogs which spot the fields, in many of the farming districts that have been neglected, is doubly profitable—the soil is taken away, and it furnishes a rich dressing for the thin and light lands.

As one might suppose, from the marshy nature of great part of the surface, snipes are very plentiful in North America. They do not differ greatly from the snipes of Europe, but they are not exactly the same; no native animal of America is exactly the same as the analogous one of the eastern continent, and man himself does not appear to be an exception to the general rule. Our limits will not admit of a full enumeration of even the known snipes of America, but we shall notice one or two.

AMERICAN WOODCOCK (*S. rubicola*). In its form and manners, this has a considerable resemblance to the woodcock of Europe, but it is smaller in size and differently coloured. The under parts are rusty red, instead of yellowish white with dusky lines; and the female weighs half a pound, and the male two or three ounces less. It is a migrant, wintering in the southern parts, and appearing in the central states about the beginning of March. It does not appear that they proceed to the very extreme north, indeed they cannot be expected beyond the woods and brush, and there are abundance of these to the northward of the great lakes, for sheltering all the woodcocks in the world.

The male of this species is ten inches long, and sixteen in the stretch of the wings; and the female is twelve long, and eighteen in extent. The upper mandible of the bill is reddish brown, with the enlarged knob or nail black; and it is about two inches and a half in length, and projects a tenth of an inch beyond the truncated tip of the lower one. Both mandibles are grooved. The front, a streak over the eye, and all the under parts of the body, are tawny red, the sides of the neck ash colour. The top of the head black, with three bands of brownish white. The back and scapulars deep black, with narrow rust coloured margins to the feathers; but these parts pass into bluish white at the edges; and all the back has zig-zag lines of black on the lighter parts. The quills are brown, and the insides of the wings reddish rust colour. The tail feathers are black, with a row of reddish brown spots along the outer web of each, and the tips narrow and of a pale drab colour. The under side of the tail-feathers is silvery white. The legs and feet are flesh colour; and the eyes, which are situated much further back than in the European woodcock, are very prominent, and of a deep black colour. The weight is generally rather less than six ounces. In the female, the colour on the back is of a paler tint, and there are dusky bars on the under sides of the wings. These differences in colour, together with the great disparity in size, has occasioned these birds to be considered as two distinct species.

Woodcocks breed earlier in the season in America than they do in Europe. Wilson mentions that nests with eggs have been found in February, but that the usual time is early in April. In consequence of this the birds are on the ground, and sporting commences as early as July, through which month and the two following ones, the best season for them continues. In Britain

they do not make their appearance on the low grounds till the end of September, and they are not numerous till November, the time at which the American ones quit the middle states, and proceed to the south. The following description of the manners of these birds, by Wilson, is worth quoting as illustrative, not of them only, but, with slight variations, of the whole genus. "The woodcock is properly a nocturnal bird, feeding chiefly at night, and seldom stirring about till after dark. At such times, as well as in the early part of the morning, particularly in spring, he rises, by a kind of spiral course, to a considerable height in the air, uttering at times a sudden *quack*; till having gained his utmost height, he hovers around in a wild irregular manner, making a sort of murmuring sound, and then descends with rapidity as he rose. When uttering his common note on the ground he appears to do it with difficulty, throwing his head toward the earth, and frequently jotting up his tail. These notes and manœuvres are most usual in spring, and are the call of the male to his favourite female. Their food consists of various larvæ and other aquatic worms, for which, during the evening, they are almost continually turning over the leaves with their bill, or searching the bogs. Their flesh is reckoned delicious, and prized highly." The summer, which is much hotter, and more rainless in many parts of America, than it is in Europe, and especially in Britain, dries up the waters and hardens the earth much more early in the season. This is obviously the reason why the woodcocks, adapting themselves to the climate, breed so much earlier than those with us. In consequence of the drought, they are compelled to descend to the margins of the larger streams in July; and thus, if they bred as late as the same birds do in Europe, the young would perish for want of food, as they, like all the other ground birds, have their feet perfect, and are able to find their food long before they can fly.

SOJA (Moench). A Japanese plant, belonging to the *Leguminosæ*, the seeds of which are made into a sauce, which is preferred to the kitjap of China; "both, however, are imported into England in large quantities, and are here known as soy. In bond it is worth six shillings a gallon, but, after it has been adulterated, it is sold at three shillings a pint."—(Burnett). This plant was the *Dolichos Soja* of Linnæus.

SOLANDRA (Linnæus). A genus of evergreen and climbing shrubs, having pentandrous flowers, and belonging to *Solanææ*. These are favourite stove plants, and if potted in loam, encouraged to grow into bulk, and afterwards kept dry till their leaves fall off, they will soon produce flowers. They are easily increased by cuttings.

SOLANÆÆ (Linnæus). A natural order, containing thirty-three genera, and above four hundred and sixty-one species. Although there is great diversity of properties in this order, it is still a truly natural one. For notwithstanding the deadly nightshade and the esculent potato, the acrid capsicum and the bland tomato, the wholesome egg-plant and the poisonous tobacco, with the stramonium, the henbane, the mandragora, and various other equally deleterious or equally innocuous plants, are found here associated, they afford evidence of relationship. The deleterious principles prevalent in the *solanææ* are narcotics of a peculiar kind. Several of these have been separated, and named from the plants in which they are found, as *atropine*, *solanine*, &c. The narcotic principle

which is so deadly a poison in the mandragora and belladonna, is present in the potato and the egg-plant, but in the latter in such small quantities as to be altogether innocuous when prepared for food.

Many plants belonging to this order are very handsome. The *verbascums*, *daturas*, and *solandras*, are all plants of great beauty, and mostly bearing pentandrous flowers; they are also almost all easy of cultivation and propagation.

SOLARIUM (Lamarck; *TROCHUS PERSPECTIVUS*, Linnæus). Linnæus and his disciples considered this genus to be a species of *Trochus*, with which it certainly appears nearly allied, particularly when compared with such of them as have the base terminating in a sharp edge at the outer circumference. In form this genus also resembles the *Planorbis*, and from the examination of some fossil species, it is very difficult to draw a distinct line between them. Lamarck's division, however, cannot be mistaken for either of the above-mentioned genera, the umbilicus of the shell being always dentated or crenated at the edge of the internal whorls. These shells are of an orbicular depressed conical form; the umbilicus very wide, with dentated spiral whorls running interiorly from the summit to the margin; the aperture is nearly quadrangular, and there is no columella. The writer has seen a calcareous operculum said to belong to this genus. In appearance it closely resembles the thick stony operculum of many of the *Turbinæ*, but its shape was more quadrangular, which seemed to characterise it as belonging to this genus. These molluscs sometimes attain a considerable size. We have seen them three inches in diameter; they are elegantly sculptured, and delicately marked with black and straw colour, and the beauty of their symmetry is not surpassed by any other shell. The perspective *Solarium* is from the Chinese and Indian seas, but one small species of *Solarium* is found in the Mediterranean. Several fossil species are known and described. The animal constructing this shell appears unknown, or at least it is so to us, no author we have met with giving any account of it. This occurrence will now become less frequent, as the present impetus given to this branch of natural history will enable the scientific writer to examine the animals as well as their habitation; and from such an examination the only true classification can be accomplished.

SOLDANELLA (Linnæus). A genus of humble alpine herbs, but bearing beautiful pentandrous flowers, and belonging to *Primulacææ*. They should be in every flower-garden, thrive in peat-earth and loam, and are suitable for rock-work or placed in small pots; division or seeds.

SOLIDAGO (Linnæus). A numerous genus of perennial herbs, mostly natives of North America. They have invariably yellow and rather showy heads of flowers, and belong to *Compositæ*. In English lists they are called Golden Rod, and are usually planted in shrubberies, as they are tall-growing plants.

SOLOMON'S SEAL, is the English name of the *Polygonatum vulgare* of Desfontaines. The flowers are hexandrous, and the genus belongs to *Smilacææ*. Common in every collection, and increased by division.

SOMMITE. This highly interesting mineral is the rhomboidal felspar of Mohs and the nepheline of Haufy and Werner. It is generally of a white

colour, and the primitive form is rhomboidal. The most common secondary forms are exhibited in the sketches beneath.

Sommite is strongly translucent, and one of its most curious properties is that a few moments' immersion in nitric acid will produce a cloudy and waved character throughout. The finest specimens are brought from Monte Somma near Naples.

SOPHORA (Linneus). A genus of very ornamental plants, natives of Eastern Asia, Siberia, and of the tropical parts of America. The flowers are decandrous, and the form of their fruit associates them with *Leguminosæ*. *S. Japonica*, a very handsome species, requires protection from frost when young, but becomes hardy enough when old. Seeds.

SORGHUM (Willdenow). A genus of tropical cereals, bearing polygamous flowers, and belonging to *Gramineæ*. These plants produce the small grain called Indian millet, and for which it is cultivated in most warm countries. In the West Indies it is called Negro Guinea corn.

SPAR. This name is employed to designate some of the most beautiful mineral productions. Thus, *calcareous spar* is of an obtuse rhomboid shape, and in its secondary characteristics it forms fine stalactites, of which the Derbyshire caverns furnish magnificent specimens. A beautiful fibrous variety of carbonate of lime, called *satin spar*, is found in Cumberland; and another still more beautiful, called *Arragonite*, is found in Arragon in Spain.

Flour spar is a mineral found in many parts of the world. In Derbyshire it is called *Blue John*, and it there varies much in its colour. It is highly phosphorescent at a red heat. In its ordinary state it is made into ornamental vases, &c.

SPARAXIS (Ker). A genus of bulbs, natives of the Cape of Good Hope, and belonging to *Iridææ*. The species thrive well in light sandy soil, and with a covering in winter, stand and flower well on a south border, if planted deep.

SPARGANUM (Linneus). A genus of British aquatics, belonging to the natural order *Typhineæ*. The plants are known as the bur reed.

SPARROW (*Passer domesticus*). Though the common house-top sparrow is a bird which every body knows, as it is the only wild bird that inhabits the very heart of the largest cities, yet there is an interest about it which demands a short notice. It is the closest companion of man among all the feathered race. There are others which come to the neighbourhood of houses in the evil day, when food fails them in the fields or the woodlands, among which is the common red-breast. But the sparrow is a more close and constant companion, keeping company with man summer and winter, and never being found at any distance from a human habitation. To find a sparrow on the hill, or in the forest, is out of the question, and it is rare to meet with one upon a wide common, or a large field, when distant from the farmhouse. Thus, to observe a sparrow, is almost as sure a sign that there is a dwelling near as to observe a cat.

What should make this particular bird so constant an attendant at houses is a point not very easily settled, but the fact cannot be doubted. It is not for the mere purpose of getting safe footing on the house-tops, and nestling under the eaves, for the sparrow can perch upon trees, and also build its nest there, though it prefers a situation where the nest can be under cover. When it does build in trees its style of build-

ing is very similar to that of the tree-sparrow; and yet the latter does not appear to have any propensity to collect about houses, but rather the reverse. During the night the sparrows roost in trees, or in any elevated shelter that they can find about buildings or banks. The race always nestle in holes when they can, and never have a nest quite open at top; for if there is not a natural covering to throw off the rain, they make an artificial one, and they appear to do this jointly for their own shelter and that of their young; for, if the nest is left undisturbed, the pair that built it occupy it as a house during winter as well as for a nursery in the warm season. The young are, however, sent abroad to seek winter protection for themselves.

Sparrows are birds of very ardent temperament, and therefore they consume a very great deal of food. In the spring they are very destructive to gardens, as they not only eat the seeds of vegetables, if these are not deeply covered with earth, but they watch the young plants, and pull them out of the ground, so that, in the course of a single morning, all the young plants in a bed of radishes will be left lying on the surface; and where small seeds of cabbages, onions, and other plants are grown, they are equally destructive. But really the advantage and the mischief very nearly balance each other, at least in some of these cases; for the covering up of the plants with straw or branches, till they have formed their leaves, is worth all the labour that it costs, even if there were no sparrow to be guarded against. But the labours of the sparrows at other times are very valuable, and the number of insects and larvæ which they consume is immense—quite sufficient to eat up the whole of the vegetation, were it not for the labours of these birds. They thus afford another proof of the adaptation of the whole of nature to the use and advantage of man; and if there is any animal, whether large or small, which thus attaches itself to the human race, it will always be found that that animal consumes something that is more destructive than itself; and the sparrow is one of the cases in which human labour cannot be substituted.

SPARTINA (Schreber). A genus of perennial herbs, belonging to *Gramineæ*. *S. stricta* is a native of Britain, and found in salt marshes.

SPARTIUM (Linneus). The spartium was once a very numerous genus, now reduced to one only, viz. *S. junceum*, the Spanish broom. It belongs to *Leguminosæ*.

SPARUS, or rather SPARIDÆ—the sea-bream family—the fifth of the families into which Cuvier divides the spinous-finned fishes. They have some resemblance to the *Perches*, and still more to the *Scienoidæ*; but they have also characters of their own, on account of which they deserve to be treated as a separate family. The general characters of the family are: no teeth on the palate; the general form of the body like that of the *Scienoidæ*; the body covered with scales of greater or less size, but no scales on the fins; the muzzle is not turned, and there are no cavernous enlargements in the bones of the head; they have no toothings, and no spines to the gill-lid, and they have never more than six gill rays. They are divided according to the form of the teeth, and in this way they admit of being formed into three families. The first of these, the *Sparidæ* properly so called, have the teeth in the sides of the jaws, round and flat in the crowns, like a sort

of pavement, and they admit of subdivision into five genera. Of these, and also of the other tribes, some occur more or less rarely on the British shores, and some not at all. We shall confine our notice chiefly to those which are found on the British shores. Taking them generally, the fishes of this family are not much esteemed for the table.

SARGUS—the Sargue. There is no English name for this genus, and the fish, we believe, has not occurred on the British shores. There are, however, several species in the Mediterranean, and they also occur on the shores of the American States, where they are called sheep-heads. They have the front teeth with trenchant edges, something similar to those of man, but they differ in these respects, for some have them divided into several points; the cheek-teeth are always in the form of a pavement; the colour is in general silvery, marked by cross bands of black.

CHAYSOPHRIS—Gilt-head. The generic characters are: the body compressed laterally, and deep in the vertical section; only one dorsal fin, with the rays partly spinous and partly flexible; six conical incisors in each jaw, and oval teeth, like a pavement, in the sides of the mouth, three rows below and four above; the cheeks and gill-covers scaly, and six gill-rays.

The common gilt-head (*C. aurata*) is the one best known. It is exceedingly abundant in the Mediterranean, and not rare on the west coast of Spain, Portugal, and France. It is occasionally found on the south coast of England, and strays, sometimes wanders, along the west coast, and even the east. They are, however, fishes of warm climates, and cannot bear the cold of winter very far to the north. The generic name, and its synonym gilt-head, have been given on account of the bright golden yellow of the space over the eyes in these fishes.

The back is of a silvery grey, shaded with blue, the belly shining steel blue, and the two colours are parted by golden tinted lines on the sides; the fins and tail are bluish, the latter darker than the others; the scales stand up at each side of the dorsal and anal fins so as to give them the appearance of being seated in grooves; the body is sloped at the anterior end of the dorsal-fin; the head high and short; the eyes have golden irides and black pupils; the gold spot over the eye is crescent-shaped, and there is a violet spot on the upper edge of the gill-lid. This fish rarely exceeds a foot in length. Shelled mollusca form a principal part of its food; and its teeth, and the action of the jaws, are so powerful that it can break the hardest shells—mere crushing, not mastication, is, however, the proper function of its very powerful mouth.

There is another species which has the teeth much smaller than the one which has been noticed, the *C. micradon* of Cuvier. It is of the same colour as the common gilt-head, but smaller in size, and with only two rows of teeth in the lower jaw; the great oval cheek-teeth are wanting, but still the habit of the fish is nearly the same as that of those with the larger and more numerous rows of teeth, namely, that of a feeder upon shelled mollusca and various species of sea-weed.

PAGRUS—Braise. The characters of this genus are nearly the same as those of the gilt-head, only the teeth are different. There are four or six strong conical teeth in the front of each jaw, with two rows of smaller ones behind them, and two rows of molar

teeth in the lateral parts. Like most others of the family, the fishes of this genus feed upon sea-weed and crustacea and shelled mollusca. They are consequently found in the deep water on the rocky shores and not on the banks or the beaches. They come to the shores in the summer and autumn, but retire to the deep water in the winter and spring. Like most of the family, they are impatient of cold, and therefore more abundant in the low than in the high latitudes. In the Mediterranean there appear to be many species; and there is one, the common braise or becker (*P. vulgaris*), which is not rare on some of the British shores. The muzzle is blunt, as in the gilt-head; but the body is a little longer in proportion. A small part of the dorsal and the anal fins is concealed by the projecting scales at their bases. This peculiar application of the scales tends much to stiffen the fins at their bases, and thus enables the fish to maintain its place steadily in the turbulent waters in which it feeds, and where there are currents and turmoil more violent and to a greater depth than where the bottom is comparatively level. Silvery white with a tinge of red are the general colours of the braise; and there are no metallic glosses on the head, or dark spots on the gill-covers at the commencement of the lateral lines, as in the gilt-head; the membranes of the fins are also white, with a tinge of red; and the rear of the dorsal is rather darker than the rest. The pectorals have generally a tinge of violet, and sometimes a red spot, near their origin. The eyes of this fish are very large, with the irides of a golden-yellow colour, and the gape is wide, indicating the voracious disposition of the fish. The authorities indeed say that the name *Pagrus* is expressive of this, being derived from the Greek *phagōn*, a devourer; but there are many fishes which are much more voracious than this one, though as its food, the seaweed part of it, is not nearly so nutritious as the animal subsistence of the greater number of fishes, therefore it needs an increase in the quantity. It is doubtful whether all the fishes caught on the British shores, and called by the local names of this one, are of the same species, although there is not much doubt of their belonging to the family of the *Sparidae*, which are not very likely to be mistaken for another.

PAGELLUS—Sea Bream. The characters of this genus are: the front teeth conical, small, and numerous; the laterals also small and round in their form; the first part of the dorsal with spinous rays, and the remainder with soft ones; they are abundant in the Mediterranean, and two are enumerated in the list of the British fishes, one not rare on various parts of the coast, and the other very much so. The one which is found in abundance on some coasts is not much esteemed for food when dressed by the common methods; but Mr. Yarrell praises it when broiled in such a manner as that the scales and skin shall retain all the juice. This is a good plan with all fish, and a most essential one in the case of the wide ranging spinous fishes. Thus a perch, when boiled or dressed in any way by which the substance can be let out, is dry and tasteless, and eaten for the sauce which is used with it fully as much as for the fish. But after a hard morning on the hill, "first catch" a perch, next set up three sticks gipsy fashion, and suspend him by the tail, taking care that no part of the skin is broken, and that he is simply wiped, not soaked in water; then involve him in the flame and smoke of sticks till the skin and scales form a

black crust, after which finish the dressing more slowly. Roll him in a clean cloth to cool a little, and by gentle pressure on the cloth the crust will peel off; and you will, in all time coming, be able to tell what a perch really is. It is the same in all the wide ranging *Acanthopterygii*; and as matters are usually managed, we have an exemplification of the adage "food from above, cooks from below."

The jaws of the sea bream are short and of equal length, and the head is also short, and descends suddenly to the point of the upper jaw; the sides of the head are scaly; and there is a portion of the anterior part of the gill-lid of a dull silvery metallic appearance; the upper part of the body is reddish-grey, the sides golden-grey, passing into white on the belly; the dorsal and anal fins are brown, the pectorals and the caudal red, and the ventrals grey. It is very common on some parts of the south coast of England, and on various parts of the east coast. It is also common on some of the shores of Ireland; and it is not unknown as far to the northward as Norway. They are most common in the summer and autumn, about the latter end of which season they deposit their eggs, and then retire into the deep water till the summer again comes round. The young, which are called *chads* on the coast of the Channel, appear then in vast numbers as early as January, at which time they are about an inch long. As is the case with all sorts of fry, they are eaten in great numbers by the larger fishes; and they themselves are very voracious in proportion to their size. They are easily caught with hook and line, as they bite at any kind of bait. Indeed, when adult they are among the most miscellaneous of fishes in their feeding. They browse the finer sea-weed from the rocks, and they eat small fishes, crustacea, and shelled mollusca; but it does not appear that they swallow very large fishes, as their mouths, contrary to those of the majority of fish, are much more of a browsing than of a swallowing character. Their side teeth are, however, very improperly called molars or "grinders," for the jaws merely open and shut without any lateral motion, which is the true grinding one. The other species which has been noticed as a rare straggler on the British shores, is

THE SPANISH BREEM (*P. erythrinus*). It has been but recently observed on the shores of this country, and that only on the south; and we had best allow Mr. Couch to give his own description of it. "It is the size of a small sea-bream; the body rather more slender; head flatter on the top; eyes smaller, inclining to oval; before the eye the head is more protruded; the mouth with a under gape; front teeth as in the sea-bream; grinders more broad and blunt; scarcely a depression before the nasal orifices, though in the sea-bream they are conspicuous; fins as in the sea-bream, even to the number of rays, except the pectoral, which in the sea-bream reaches opposite to the third ray of the anal fin, in this only to the vent; there is no lateral spot."

There are many species of this genus in the Mediterranean, some of them with the muzzle larger than in those that have been described; some of a silvery colour, and others the same in the ground, with cross bands of black.

DENTEX. These are Mediterranean fishes, which very rarely indeed wander as far as the British shores; and at present there is only one recorded specimen, which was caught off Hastings, and brought

to the London market, in April, 1805, which was obtained and described by Donovan. This was

Dentex vulgaris—the four-toothed species, which may be considered as the typical species of the genus. The specimen above alluded to was a fish of considerable size, being two feet and a half in length; but in the Mediterranean they are often found three feet in length, and weighing from twenty to thirty pounds, while the one mentioned weighed sixteen; and it must have been in good condition notwithstanding its long journey, for twenty-eight pounds is the proportional weight of a three-foot fish, when a two feet and a half one weighs sixteen, that is, taking them as the cubes of the lineal dimensions, which is the accurate mode of estimation.

The characters are, the body deep in the vertical section, but compressed laterally; the fins in number and arrangement as in the rest of the family, but with one very strong spine in the part of the ventrals, and thence in the anal; the head large, all the teeth conical, and placed in a single range, and four in the front of each jaw, very long and strong, resembling the canines of a beast of prey; teeth also over the gill-arches, but none on the palatal bones or the vomer; the head in front of the eyes without scales, and six rays to the gills. This fish has been long known in the Mediterranean, receiving the name *Dentex*, "toothy," from the great size and strength of the fore-teeth, which have also obtained for it the name of *Cynodon*, or "dog-tooth." As it is a fish of some celebrity in its locality, we shall quote Donovan's account of it. "A more voracious fish is scarcely known; and when we consider its ferocious inclination, and the great strength of its formidable canine teeth, we must be fully sensible of the ability it possesses in attacking other fishes, even of superior size, with advantage. It is asserted, that when taken in the fishermen's nets, it will seize upon the other fishes taken along with it, and mangle them dreadfully. Being a swift swimmer it finds abundant prey, and soon attains to a considerable size. Willoughby observes, that small fishes of this genus are rarely taken; and the same is mentioned by later writers. During the winter it prefers deep waters; but in the spring, or about May, it quits this retreat, and approaches the entrance of the great rivers, where it deposits its spawn between (in?) the crevices of stones and rocks. The fisheries for this kind of sparus are carried on upon an extensive scale in the warmer parts of Europe. In the estuaries of Dalmatia and the Levant, the capture of this fish is an object of material consideration, both to the inhabitants generally as a wholesome and palatable food, when fresh, and to the mercantile interest of those countries as an article of commerce. They prepare the fish, according to the ancient custom, by cutting it in pieces, and packing it in barrels with vinegar and spices, in which state it will keep perfectly well for twelve months." This appears to be the only, or at all events the best, way of preserving the flesh of these fast-swimming spinous fishes generally; and though there does not appear to have been much, or indeed any, attention paid to it, it seems that the flesh of all fishes which gets dry in the ordinary modes of cooking cannot be advantageously preserved by salt. The salting is more successful in the soft-finned fishes, and some of the cartilaginous ones can be preserved by simply drying them, or at most by watering them once or twice with salt water.

CANTHARUS. The characters of this genus are:

the body compressed, and deep in the vertical section; only one dorsal fin; the teeth not large, but very numerous, of a conical form, and placed in several rows, the external ones larger and more curved than the others; the gape not very wide; and the gill-rays six in number.

The species of this genus are not numerous, even in the Mediterranean, which appears to be the headquarters of the family of the *Sparidae*; and there is only one known as a British fish, to which our notice must be restricted. This one is

The Black Bream (C. griseus). This fish cannot be said to be rare, and yet it is not a very common one, even upon the coasts of the Channel, where spinous fishes are much more abundant than on any other part of the coast. The end of summer is the time when they are most plentiful, and then they are very bold, and resort close to the shores. They are very voracious fishes, biting readily at any kind of bait. They are not of very large size, a foot and a half being about the average. The general colour of the body is bluish-grey, with longitudinal stripes of light and dark, and the scales relieved at the edges with lighter colour than the central parts. The dorsal fin is brown, and all the other fins are of the same colour as the body, only darker in tint. This species is not uncommon in many parts of the Atlantic, but it does not, we believe, occur in the high latitudes.

There are a few more members of the family, which differ from the last mentioned by having the teeth more or less trenchant, the body of an oval form, and much compressed, and the colours bright, generally with golden coloured stripes upon a silvery or bluish-brown ground, with metallic lustre.

SPATALLA (Dr. R. Brown). A genus of evergreen shrubs, natives of South Africa. The flowers are tetrandrous, and the genus is included among the *Proteaceæ*, of the general character of which the different species largely partake, requiring exactly the same treatment.

SPERCHEUS (Fabricius). A curious genus of coleopterous insects, placed in the family *Hydrophilidæ*, having the body short, oval-hemispheric, and very gibbose; the antennæ only six-jointed; the mandibles bedentate, and the legs formed for walking. There are but very few species, the type *Sp. emarginatus*, Latreille, found, but very rarely, in damp situations at the sides of water.

SPERGULA (Linnæus). A genus of annual and perennial herbs, mostly natives of Europe. It belongs to the twelfth class of Linnæus, and to the natural order *Caryophyllææ*. They are mostly weeds, though, under the name of *spurry*, one of the species is cultivated for sheep food.

SPERMACOCE (Linnæus). A genus of herbs, chiefly annuals, for the most part natives of the tropics. They belong to tetrandia monogynia, and to the natural order *Rubiaceæ*. The English name is button-weed. Some of the species are met with in our stoves, where they are easy of management.

SPHACELE (Bentham). A pretty plant from Chili, belonging to *Labiata*, and which succeeds well under the ordinary greenhouse management.

SPHÆRIDIDÆ (Leach). A family of minute coleopterous insects belonging to the section *Pentamera*, and related to the *Hydrophilidæ*, and dung-feeding *Lamellicornes*, having the body short, rounded, and convex; the prosternum pointed behind, the

tibiæ spined, the antennæ eight or nine-jointed, and the maxillary palpi a little shorter than the antennæ. These insects are of small size and very frequent occurrence, residing in the midst of the excrement of cattle and horses, round which they may be observed hovering almost as soon as it is fallen. Some of the species reside at the edges of water. There are two genera; *Sphæridium*, Fabricius (anterior tarsi dilated in the males), of which the *Dermestes scarabæoides* of Linnæus is the type, and which is a very common insect of a shining black colour, with a blood red spot at the base of the elytra, and the extremity pale reddish. The other genus is *Cercyon*, Leach, having the anterior male tarsi simple. The species are very numerous and minute.

SPHÆROLOBIUM (Smith). A genus of evergreen shrubs, natives of New Holland, and belonging to *Leguminosæ*. They are greenhouse plants, and are increased by cuttings.

SPHEGIDÆ (Leach). A family of hymenopterous insects belonging to the section *Aculeata*, and subsection *Fossoræ*, having the collar narrowed in front so as to appear like a joint, and the basal joint of the abdomen, and sometimes part of the second, narrowed into a long and slender footstalk or peduncle of considerable length; the anterior wings have always three complete submarginal cells, and the commencement of a fourth. The habits of these insects are similar to those of other fossorial families. (See the articles *Fossoræ* and *HYMENOPTERA*.) They are exceedingly active, their stings are very powerful, and they are altogether the most interesting, as well as curiously constructed of the fossorial tribes. The genera are *Ammophila*, *Miscus*, *Sphex*, *Pronæus*, *Chlorion*, *Dolichurus*, *Ampulx*, *Podium*, and *PELOPÆUS* (which see); those printed in italics containing British species.

The genus *Ammophila* of Kirby is distinguished by the elongated form of the lower jaw and lip, forming a long kind of tongue elbowed about the middle; the mandibles are toothed, and the palpi filiform and of nearly equal length; the second submarginal cell receives two recurrent nerves; the abdominal peduncle in some of the species is very long. There are several British species (some of which appear to be doubtful as regards their rank as species). They are of large size, and generally of black colours, with the abdomen more or less red. The type is the *Sphex sabulosa* of Linnæus, a very abundant species, varying from two-thirds of an inch to an inch in length. Another equally common species is the *Amm. hirsuta*, of the economy of which the following details have been published in the new part of the Transactions of the Entomological Society. The writer having disturbed one of the females whilst engaged in forming her nest, "she quitted it and proceeded to commence a fresh one close to the former; when she had proceeded about the depth of her head, I observed that her jaws constituted her chief tools; with these she brought up particles of sand and bits of stone, creeping backwards to the mouth of the cell; when a little mound of sand had been accumulated, she set about brushing it farther from the orifice by means of her fore legs, and it was droll to see the celerity with which these limbs were moved, and the shortness of the time required to remove the sand which was thrown with force beyond the body of the insect, the head of which was kept near to the opening of the burrow. In this manner she proceeded

to a depth greater than the length of her own body, so that she was entirely hidden from view for several moments at a time, reappearing backwards as usual, with her mouth laden with sand and stone. During these operations, a considerable buzzing noise was occasionally made. Notwithstanding my interruptions she proceeded in her work, and at length flew off, and I shortly afterwards observed her at about a yard's distance from her burrow engaged in dragging along a large smooth green caterpillar, found I think upon the broom, and being that of one of the *Noctuidæ*, and I noticed that it was only by the assistance of her jaws and fore legs that she had secured her prey, the latter, which served her as arms, being clasped round the body of the caterpillar, and the four hind legs used in walking. When about half a yard's distance from the burrow she set down her prey, and flew off towards her nest to see that all was right, and returning again seized the inactive caterpillar as before, and ascended the bank in a more direct and easy way than she had previously gone. On arriving at the mouth of the cell she again laid down her prey and crept into the hole, but instantly reappeared head foremost, seized the head of the caterpillar with her jaws, and dragged it down. As these proceedings did not occupy more than a quarter of an hour, I feel inclined to think, that as there was not sufficient time to dig a deep burrow, the cell thus made was intended only for the reception of a single larva, and that, as the sand was very loose, and so little time occupied in the operation, a fresh nest is made for each larva. †

"*Ammophila sabulosa* (*Vulgaris*, Kirby) was also flying about the same situation: its attitudes when in flight are very droll, the abdomen being held out at an angle with the rest of the body. In walking I observe that the hind pair of legs are almost useless, being dragged along behind the others, and nearly motionless. This species differs from the former in its mode of digging its burrow. It indeed uses its jaws like the *Amm. hirsuta* in burrowing; but when they are loaded, it ascends backwards to the mouth of the burrow, turns quickly round, flies to about a foot distance, gives a sudden turn, throwing the sand in a complete shower to about six inches' distance, and again alights at the mouth of its burrow." (Trans. Ent. Soc., vol. i., p. 200.) Mr. Shuckard, in his valuable Essay on the Indigenous Fossorial Hymenoptera, just published (p. 77), has observed the female of this species dragging a very large inflated spider up the nearly perpendicular side of a sand-bank, at least twenty feet high; it dragged its prey backwards, and solely by its mandibles.

The genus *Miscus* differs from the preceding in having the third submarginal cell petiolated; it contains one British species, *M. campestris*. The genus *Sphex* has the mandibles large, curved, and bidentate; the lower parts of the mouth rather short and elbowed

nearly at the lip, the second submarginal cell receives the first recurring nerve, and the third receives the second. This is a very extensive genus, comprising many large and fine exotic species, together with *Sphex flavipennis*, of which a single British specimen has been captured. It is in the collection of J. F. Stephens, Esq.

SPHINGIDÆ (Leach). A family of large lepidopterous insects, belonging to the section *Crepuscularia* of Latreille, having the antennæ prismatic, and terminated by a small bundle of scales; the palpi are large, and closely clothed with scales, the third joint being very minute; the body is in general robust, and the flight very powerful; the spiral tongue is also often of very great length. These insects are ordinarily known under the name of hawk-moths (see **HAWK-MOTH**). The genera are: *Sphinx*, *Acherontia* (see **DEATH'S HEAD MOTHS**), *Smerinthus* (which see), and *Deilephila* (which see). The genus *Sphinx* comprises those species which have the wings entire, the antennæ acute at the tips, the spiral tongue very long, and the antennæ not clavate. The species are generally of large size; the abdomen is generally gaily varied with coloured transverse bars, but the wings are often of dull colours; their flight is extremely rapid. The British species are: *Sph. convolutus* (the *Convolutus Sphinx*), *Sph. ligustri* (privet hawk-moth), and *Sph. pinastri* (pine hawk-moth). Several others have been introduced, but they are considered as doubtful natives, being probably importations. A subgenus, containing the beautiful *Sph. neri*, was published by Mr. Curtis on the first of February, 1837.

SPIDER. The ordinary English name of a very extensive tribe of arachnidous insects, constituting in the Linnæan system the genus *Aranea*, but forming, in the modern arrangements of Latreille and Leach, a distinct order, named *Araneides* by the former, and *Dimerosomata* by the latter, divisible into several families and numerous genera. In the article **ARACHNIDA** will be found numerous details relative to the structure and physiology of the order; and in the article **EPEIRA** is given a sketch of its distribution into families. The present article will, therefore, be more exclusively confined to the details of the economy and habits of this interesting but too much neglected tribe.

An insect destitute of a distinct head, and wanting antennæ, in which one half of the body is suspended from the other by a very slender peduncle, in which the integuments are so soft as not to bear the least pressure, whose limbs are so slightly attached to the body that they fall off at a very slight touch;—an insect thus destitute appears but ill adapted of itself either to escape from the dangers which threaten it on all sides, to secure for itself a sufficient supply of food, or to protect its brood from injury. Such are the conditions of the existence of the spider in general, which, however, are amply compensated by means bestowed upon them by an all-wise Creator for their apparent want of power, and by which they are not only enabled to entrap and secure insects much larger than themselves for their subsistence, but also to construct habitations for their abodes, and to defend their offspring against the inclemencies of the seasons and the attacks of their enemies. The means by which these effects are produced are exceedingly simple; namely, the secretion of two fluids by internal organs, one of which is a gummy fluid exuding from an apparatus

near the extremity of the body, and the other is of a poisonous nature, and flows from the mandibles. With the first they are enabled to construct webs or nests of various texture and form, serving for the purposes of habitation, of traps for their prey, or of covering for their eggs and young; and with the latter they are enabled to destroy insects larger than themselves in a very short time for food.

A very great diversity exists in the modes in which the nests or webs of these insects (for we consider them as such for the reasons given in our general article INSECT) are constructed, and the situations in which they are placed. The internal apparatus for secreting the silk is lodged within the abdomen near its posterior extremity, and consists of a small number (four or six, according to the species) of twisted, elongated, and unequal-sized vessels, being thickest in the middle, at the extremity of which is a great number of similar vessels, but of a much smaller size, and considerably shorter, and which are pressed against each, uniting in a common base, which is in connection with the *external* apparatus. The latter is visible to the naked eye on the under side of the abdomen, appearing, when pressed, in the shape of a small star, having several small oval-shaped or sub-conical appendages, teats, or spinnerets, as we may call them, placed near the extremity of the body, their extremities, when at rest, being brought into contact. In the greatest number of spiders there are four of these spinnerets, but in some there are six, two of which, however, appear to have neither pores nor papillæ. The matter discovered in the internal vessels is analogous to a gum, or transparent paste. In *Epeira diadema* it is of a yellow colour; in *Clubiona atrox* white; and in *Aranea domestica* brown. It is not soluble in spirits of wine or in water; it breaks when it is attempted to be bent, and, like glass, can only be made flexible when it is divided into very thin threads. On examining the spinnerets more minutely, it will be found that each is surrounded with several series of minute bristles, like points, about one thousand to each spinneret. From each of these points or spinnerules is discharged a thread, so that it may be easily conceived of what an immense number of distinct threads the apparently simple thread of the spider consists. According to a calculation made by Leeuwenhoeck, the celebrated microscopist, on a young spider, not larger than a grain of sand, it would require four millions of the threads discharged from its spinnerules to make a cord the thickness of a hair of his beard. The first object which the spider has to accomplish is to attach her thread to some object, as the commencement of a ground-work for her future operations. In doing this it appears that she extends her spinnerets as widely as possible, presses them against the object to which it is intended the thread should be attached, and then discharges a thread from each of the spinnerules; the spinnerets are then withdrawn, and the threads, by degrees, are united into a single cord; the insect uses her hind legs as a reel to draw the threads out of her body. It appears, however, that the threads are of different kinds; for in the webs of the geometric spiders those threads, which are arranged in circles, are composed of more viscid materials than the radii, the former being evidently intended for securing the prey of the spider, and the latter serving merely as its frame-work, and destitute of gluten. This viscosity is produced by an immense number of

globules of viscid matter, arranged at visible distances along the elastic spiral lines of the net, and which are so fluid that they run together the moment they are brought into contact. Mr. Blackwall has given a calculation of the number of these viscid globules in the web of one of the *Epeiræ* of a moderate size, and which conveys some idea of the elaborate operations of the geometric spiders. The mean distance between the radii in one of these nets is about seven-tenths of an inch; there are twenty viscid globules on one-tenth of an inch, so that there are $7 + 20 = 140$ globules in a *single* line between two contiguous radii seven-tenths of an inch apart; this product, multiplied by 24, being the mean number of circumvolutions formed by the spiral line, will give 3360, being the number of globules contained on *all* the lines between two contiguous radii; this number, being again multiplied by 26, the mean number of radii, produces 87,360, the total number of viscid globules in a finished net of average dimensions. But larger nets, by a similar calculation, will contain upwards of 120,000 viscid globules, and yet the time occupied in the construction of this net is not more than forty minutes. Moreover, the threads with which the spider composes the retreat in which it takes up its abode, or the nest in which it envelops its young, does not appear to be of the same nature as the net-threads, neither are the threads of which it forms the case for its eggs similar to the former, the texture of these cases being in some species quite firm and smooth, resembling parchment. This case is also sometimes covered with a coating of loose flossy silk, which also seems of a different texture; hence it is evident that the vessels at the extremity of the abdomen, which serve for the secretion of the silk, as well as the structure of the spinnerets and spinnerules, require a much more minute investigation than has hitherto been given to them, in order to discover the precise manner in which these various kinds of silk are elaborated and discharged.

The nest of *Epeira diadema* is one of the most beautiful and most common of the spider constructions in this country, being found in every bush or tree, between hedges and shrubs, &c., during the autumnal months. The top line of this web appears to be first spun, either by attaching a thread as above described, and then carrying it along until it is of sufficient length, when it is attached to some adjacent object to which the spider has crawled, or by throwing out a floating line, whilst the spider remains stationary, the action of the air carrying this line on until it becomes attached to some object, when, in either case, it is doubled and redoubled, until it is of sufficient strength to bear the weight of the intended fabric, together with the spider itself. The other outer threads of the frame-work are then added, and then a cross line is carried from one point of the web to another exactly opposite. From the middle of this cross line the insect ascends or descends, having first glued another thread at the centre, which she draws out until she reaches the frame-lines, and then, going along the latter to a certain distance, she fastens the thread which she has been spinning to one of the frame-lines. In this manner she constructs a complete series of spokes or radii, which she then attaches together by a spiral series of transverse bars of a more glutinous thread, as above noticed. In spinning this spiral web she first attaches a thread to one of the radii, and then drawing it out with her hind legs,

ascends along the radius until she is able to lay hold of the next radius, down which she descends until she reaches the spot exactly opposite to where the thread had been attached; she then quits her hold with the hind legs, and the thread is immediately glued to the proper spot in the next radius. In this manner she proceeds until the whole of the net is completed; and it is quite an amusing sight to watch one of the small geometric spiders engaged in this construction; the rapidity with which the cross spiral threads are fixed in their proper places is quite astonishing.

Another interesting spider is the *Clubiona atrox*, which builds its web in the corners of windows, the crevices of walls, or in the branches of shrubs growing near buildings. We are indebted to Mr. Blackwall for a very valuable Memoir on the Structure and Economy of Spiders, published in the Linnæan Transactions, in which a description of this nest is given, from which the following is an extract. "On the objects surrounding the spot selected for its retreat it extends to a considerable distance, but without any apparent regularity of design, a number of fine shining lines intersecting each other at various angles, to which it attaches other lines, or rather fasciculi of threads, of a more complicated structure, and of a pale blue tint, nearly approaching the colour of skimmed milk. These compound threads or flocculi, which in exposed situations retain their delicate hue for a short period only (old webs being generally of a dull or sullied white, not at all advantageous to their appearance), are arranged on the first spun glossy lines, both in longitudinal and transverse directions. When recently produced, they adhere strongly to such insects as come in contact with them, and, though perfectly inelastic, may be drawn out into fibres of extreme tenuity. A communication between the snaro of this spider and its retreat, is established by means of a funnel-shaped tube of a slight texture, whose smaller extremity is in immediate contact with the latter, and indeed sometimes constitutes the animal's abode. Not unfrequently two or more tubes occur in the same web, by one or other of which the spider usually effects its retreat when disturbed."

The same author has noticed the curious fact that those species of spiders, which form geometric nests, are furnished with several claws on each foot, whilst some of the jumping spiders, and some others, have only two claws. In several species of *Epeiræ* it will be distinctly perceived that the inferior part of their feet is provided with several claws which have a degree of curvature, are finely pointed, and are furnished with tooth-like processes in the under side. In *Epeira apoclista* there are as many as five of these claws, which, in addition to the three upper claws previously known, give a total of eight to each foot. There is also a strong moveable spine inserted near the termination of the tarsus of each posterior leg on the under side, which curves upwards at its extremity, and which by the action of the flexor muscles is brought in immediate opposition to the claws, by means of which the animal is enabled to hold with a firm grasp such lines as it designs to attach itself to; and hence it is obvious why these spiders usually direct their heads downwards when they occupy the centre of their nets.

Spiders, in regard to the construction of their webs, may be naturally divided into two great groups, which have been named the sedentary and the wandering spiders. The latter do not construct regular webs,

but either live a vagabond life, as indicated in the article *SALTICUS*, or merely throw out a few loose and irregular lines in the neighbourhood of their nest. The sedentary spiders comprise two divisions, those which form nets and those which weave webs. The net-weavers are again divided into the geometric species, and those which construct webs of an irregular form, the meshes being at certain distances apart, but not arranged in concentric circles. This group, which is in general composed of minute spiders, is the most curious on account of the singular and astonishing variety in the operations of the species of which it is composed. The genus *Theridion* may be mentioned as the typical group. The web-weavers spin a closer material than the former, and, like the net-spinners, are divisible into two groups, the cloth-weavers which suspend their hair or mat-like webs horizontally between plants without any circular retreat (genus, *Linyphia*, &c.), whilst the other section may be called tapestry workers, suspending their webs in the angles of walls, &c., furnished with a circular retreat formed like the rest of the web. The domestic spider is an example of this division.

During the summer and early autumn months, it is not an uncommon circumstance to observe numerous long floating threads in the air, at one end of which a minute spider is found to be attached; the mode in which this is effected has been the subject of considerable discussion. Some authors contend that the spider has the power of directing these threads at pleasure towards a determined object. Others maintain that the thread is discharged independently of any influence from the atmosphere. Others again, that it is entirely electrical. But the most generally received opinion is, that the spider, directing its spinnerets in the direction of a current of air, discharges a thread which, being exceedingly light, is carried on by the air to such a length as to be able, from its buoyancy, to support the slight weight of the spider itself. Thus Gilbert White says, "every day in fine weather in autumn do I see these spiders shooting out their webs, and mounting aloft; they will go off from the finger if you will take them into your hand," although he adds, "but what I most wondered at was that it went off with considerable velocity in a place where no air was stirring, and I am sure that I did not assist it with my breath."

Leslie made the same observation on nearly thirty different species of spiders, and found the air filled with young and old, sailing on their threads, and doubtless seizing gnats and other insects in their passage; there being often manifest signs of slaughter, legs and wings of flies, &c., on these threads, as well as in the webs below. These threads are, however, often found without any attendant spider, and it is not improbable that these are threads which have been in the first instance woven amongst the grass and low herbs, which are sometimes observed to be almost completely carpeted with these productions, and which, being dried by the sun, and raised by currents of air, are wafted about in the atmosphere, until a perfect calm brings them to the surface again. In France the floating threads, which support the small spiders, are called *fil de la Vierge*, and it has been supposed that they were exclusively formed by a spider which has been named *Aranea obsecatrix*; but this is not correct, neither is the species here noticed anything else than a young and imperfectly described individual belonging to the genus *Epeira*.

Nearly all the different species of spiders envelop their eggs in a covering of silk. The mass of eggs thus protected, of the *Epeira diadema*, may be constantly observed during the winter months in the angles of walls of rooms exposed to gardens, frequented by the perfect insects, which, after impregnation, make their way into the houses for safety. These cocoons, as they may be called, differ in the different species. In some they are globular, in others oval, and in some depressed. The care with which these cocoons are guarded by some species is quite astonishing. Some of the species carry them about with them beneath the abdomen, and it is a matter of the greatest difficulty to compel the mother to quit her charge, and even then she wanders about the spot searching for it with the greatest solicitude. The egg cocoon of the very handsome species *Epeira zebra*, as well as the perfect insect, are described and figured in the Field Naturalists' Magazine, vol. ii, p. 57.

The silk of the spider has been supposed to be, on account of its strength, a material adapted for the ordinary purposes in which silk is employed, and to be scarcely inferior to that of the silkworm. M. Bon, of Languedoc, indeed, contrived to manufacture from it a pair of stockings and mittens of a beautiful natural grey colour, which were almost as strong as common silk. But Reaumur, to whom the subject was referred, considered that it was impossible to succeed with the growth of this kind of silk, on account of the great ferocity of the spiders, which causes them to kill one another as soon as they are confined together. Moreover, it would require 663,552 spiders to produce a pound weight of silk, or, if the largest species were employed, 55,296 would be requisite.

The harmony which nature has established between the colours of these insects and the places which they inhabit, must not be passed in silence. The species of *Epeira*, which weave their webs in the air, the *Thomis*, which hide themselves in flowers, and the *Sparassi*, which run over the green sward, have the body either of an uniform lively green, yellow, or purple colour, or varied with handsome markings; whilst the *Mygale*, *Lycosæ*, and *Araneæ*, which conceal themselves under stones and in obscure situations, are of brown, black, or other obscure colours, like the places where they reside. We have already in several parts of our work noticed the same harmony reigning in other parts of the insect world.

The nature of the poison of these animals, which in the commencement of this article was alluded to, as the other means whereby Nature had ensured their existence, will be treated upon in the article upon the *Tarantula* spider, which is the most redoubtable of the poisonous species.

SPIGELIA (Linnæus). A genus of two species of plants, one a tropical annual, and the other a half-hardy one, from Maryland. The flowers are pentandrous, and from their character belong to *Gentianacæ*. The *S. Marylandica* is a favourite in our collections, and is propagated by cuttings.

SPILANTHES (Linneus). A genus of tropical annuals, belonging to *Compositæ*. The *S. oleracea* is cultivated in the East Indies as a pot-herb. In British collections they are grown in rich soil, and raised from seeds.

SPINACIA (Linnæus). A genus of annual herbs, belonging to *Chenopodeæ*. Of this genus the well-known spinach is the type.

SPIRÆA (Linnæus). A genus of deciduous shrubs and perennial herbs, natives of various parts of the globe. The flowers are icosandrous, and belong to *Rosacæ*. Several of the herbaceous sorts are British, and many of the shrubs are in our shrubberies, and are increased by suckers, layers, and cuttings.

SPIRALEPIS (D. Don). Undershrubs and herbs, natives of the Cape of Good Hope, formerly included in the genus *Gnaphalium*, and belonging to *Compositæ*. The species thrive best in a mixture of sandy loam and heath mould, and are propagated by cuttings.

SPONDIAS (Linnæus). A genus of tropical fruit trees, bearing decandrous flowers, and belonging to *Terebinthacæ*. The fruit of the several species are eatable, being slightly acid and aromatic, but they are chiefly given to hogs; hence the name of hog-plum given by the colonists.

SPOONBILL (*Platalea*). A genus of stilt or wading birds, belonging to the cultrirostral family, and the last genus of that family, and the one immediately bordering on the long-billed races in Cuvier's arrangement. The characters are these: the bill very long, stout, much depressed, and enlarged and rounded to a spoon-shape at the extremity; the upper mandible channelled, and furrowed transversely in the basal part; the nostrils on the upper surface of the bill, and near to each other, open, of an oblong shape, and bordered by a membrane; the face and part of the head naked of feathers; the legs long and strong; the feet with four toes, three to the front and one to the rear, the three front ones united as far as the second joint by a deeply-notched membrane; the wings are of mean length, and the first quill a little shorter than the second, which is the longest in the wing.

The spoonbills live by the edges of the marshes, or near the sea where the ground is shaded by thick bushes, and sally from their cover only to seize the small fishes which are brought near the land by the waves. They also eat aquatic insects and small mollusca and crustacea. They are birds of gentle dispositions, and live in small troops, except during the nesting time, and even then the pairs are not very far from each other. Like most other birds of the banks and shores, they are migratory, moving in the direction of the poles in the spring, and back again toward the equator in the autumn. For their march, they assemble in larger troops, as is the case with the cranes and storks, and they either accompany these birds, or move about the same time. Even when they are in a state of confinement, they very strongly evince their autumnal migratory instinct; for though they are, during the greater part of the year, dispersed through various parts of the old continent, and even into high latitudes, yet, as autumn comes on, they collect in larger troops, and move southward. In the places where they pass the summer and rear their broods, they do not appear much on the open grounds, but prefer woods and shaded spots. They nestle in various places, according to the situation. Sometimes the nest is in lofty trees, sometimes it is in close bushes, and sometimes again it is in the tall annual herbage. It is formed externally of small sticks, and carelessly lined with vegetable fibres. The eggs are generally two or three in number, of a dull whitish colour, marked with a few russet spots. The female sits very closely during

the incubation, and when the young make their appearance, they are covered with down, and capable of running about. When they are alarmed, or otherwise excited, they make a snapping noise with their bills.

On their southern migration, the valley of the Nile is their first retreat from Europe, and they probably range from the head of that valley through the whole of the fertile parts of Africa; for they are found as far south as the region of the Cape, where they are sometimes called "serpent eaters," which name they probably deserve, as their bills, though flexible, are set with tubercles on the inside of the mandibles; and their length enables them to close at the points with great rapidity, and of course with proportionate effect.

WHITE SPOONBILL (*P. leucorordia*). This is the species which is found on the eastern continent, over which it is very generally distributed, though not in great numbers at any one place, and not very conspicuous on account of its retiring habits. Early in the morning and late in the evening are its feeding times when the weather is dry; but during rain it comes abroad at other times. As is the case with most, if not with all of the larger birds of the banks of rivers, it eats very voraciously when food can be had, but it is also capable of enduring long abstinence. This is necessary in order to adapt it to those localities in which nature has placed it. They are subject to drought and partial inundations, even during the summer. In the last of these the food of the spoonbill comes out in considerable numbers; but in the drought it disappears, or comes out only in the twilight. The total length of the full-grown spoonbill is about two feet and a half; and the length of the bill is between eight and nine inches; the plumage is white, with the exception of a large collar of reddish-yellow, which extends downwards in front, and forms a breast-plate; the forehead, the cheeks, a space round the eyes, the chin and the middle of the throat, are naked, and of a pale yellowish colour, with a shade of reddish on the lower part of the throat; the bill is black, with wavy furrows across the upper mandible, the deepest parts of which are bluish; there are triangular lateral grooves for the basal half of the length, and these pass into thread-shaped furrows for the remaining part; the enlarged portion toward the point is yellow with a border of black; and the lower mandible is wholly black, with a triangular furrow in the basal half, and a narrow groove in the remainder; the hind head is furnished with a long crest of awl-shaped feathers. The female is of smaller size than the male, has the crest on the occiput considerably shorter, and the red on the naked part of the throat is not nearly so conspicuous. The young of the year have the shafts of the quills black, and are without the crest and the reddish colour on the neck, which last does not make its appearance till after the second moult; on account of this they have been sometimes described as a different species from the old birds. Differences of appearance have been noticed in some specimens from southern Africa, but it is doubtful whether any of them are of sufficient consequence for entitling the birds to be regarded as distinct species from the common one. As a British bird, the common spoonbill can be looked upon only as a straggler, although it straggles into the south-east of England more frequently than some of the other occasionally visiting marsh birds. It some-

times appears on its northward passage, and sometimes on its southward, but there is no very clear evidence of its having, in any instance, remained to breed in the country. It probably did so, in former times, when marshes were much more abundant and marsh birds more plentiful, than they are now, but at present it cannot properly be regarded as a British bird. It is, however, by no means so rare, or, at all events, so solitary in its coming, as some others of our straggling birds. Spoonbills certainly do not come so often as to make the looking out for them an occupation in which any person in the British islands needs to engage in the hope of being certain that the result of his watching shall gratify even his curiosity; but when they are seen, they are generally in considerable numbers. Generally speaking, however, it is but a sight and away; and though the casual appearance of continental migrants upon our shores has not been very carefully noted along with the state of the weather, and the set of the wind preceding their appearance, yet there is little doubt that spoonbills, cranes, storks, and all birds of that family, which are occasionally seen with us for a little while, are blown to our shores by cross winds from the east, which compel the birds to make lee-way; and that the fatigue of struggling against these, compels them to alight and rest themselves before they again take to the wing. As a show bird in collections, the spoonbill is by no means rare; and the large size and irregular form of its bill render it an interesting bird whenever it makes its appearance. The specific use of the very peculiar form of the bill in this bird is not known with any certainty, and all that we can positively say about it is, that it is intermediate between the cultrirostral, or knife-shaped bills of the other wading birds of the family, and the flat bills of the dabbling birds, which have the toes entirely

Spoonbill.

webbed, and are launched upon the waters. As little do we know the precise part which these birds act in the general economy of nature; but from their general distribution, their size, and their power of

wing in migration, we are led to conclude that it must be an important one. The flesh of the spoonbill is more agreeable as food than that of most others of the same family. It wants the rankness which is commonly indicated by what is called a "fishy taste"—though any thing but like the taste of fish; and in this also it approximates to the flat-billed birds, the greater part of which are both wholesome and palatable.

THE ROSEATE SPOONBILL (*P. ajaja*), is a native of South America, and considerably smaller in size than the spoonbill of the eastern continent, though, according to the accounts, its habits are much the same. Its general plumage is of a rosy tint, and the upper parts of the wings and the coverts of the tail are red, of a tint rather bright. It is a native of South America, found in the valleys of the great rivers, and also, on the level plains which are subject to inundations in the rainy season. In old age the red tints of the plumage fade, and the old ones are nearly all over of a dull white colour. The bill is yellowish-green, but dull whitish in the dead subject, and also, as is said, when the bird is alarmed. It is said to be a most assiduous and successful fisher, and to stand in the water up nearly to the tarsal joints, sweeping around it in semicircles, and very dexterously catching at the fry and small fishes that come within its reach.

SPOROBOLUS (Dr. R. Brown). A genus of tropical herbs, bearing triandrous flowers, and belonging to *Gramineæ*. None of them are cultivated.

SPREGELIA (Smith). A pretty flowering evergreen shrub, from New Holland, belonging to *Euphorbiæ*. The plant thrives best in a shady situation during summer, and at all times requires to be cautiously watered.

SQUALUS, the common systematic name of the sharks. See the article SHARK.

SQUAMIPENNES. The name which Cuvier has given to his sixth family of spinous-finned fishes, and which is given them on account of their fins being covered with scales (*Squamæ*), not only on the parts which have soft rays, but frequently also on those that have spinous ones. They were all included by Linnæus in the genus *CHÆTODON*, in consequence of the hair or bristle-like form of their teeth; and we have given a short general sketch of the family under that title. We now revert to the subject for the purpose of introducing a representation of one of the most singularly formed of the genus; and we may at the same time mention that, notwithstanding the singularity of their forms, these fishes are, in point of colours at least, among the greatest living beauties of the sea. The ground colour of their bodies is generally silvery, with a very rich metallic lustre; but this is marked with every colour that can well be named, and always of the most glowing tint. They show clearly the intimate connexion which there is between those beams of the sun, which are the immediate cause of the appearance of the colours, and the modification of the surface, by means of which the coloured light is reflected to the eye of the observer. No fishes of the high latitudes have any colours so brilliant as are found upon these, neither have any which inhabit the depths of the tropical seas, or range over them in their breadth. These fishes remain near the shores and rocks in the shallow waters, and they are always near the surface. They are chiefly small fishes; but

their flesh is, generally speaking, as wholesome and palatable as their colours are beautiful; and, from the nature of their haunts, they are easily captured, though some of the species have formidable spines, by which they wound those that incautiously handle them.

The following is a representation of the chelmon which remains near the aquatic vegetation and shoots the flies, by projecting upon the fly one large drop of water, which brings it down to the surface, where the fish swallows it.

This fish is found indiscriminately in the salt water, and at a considerable distance up the rivers.

C. rostratus.

One very singular member of this family is the buffalo fish of the oriental isles, so called by the Malays, who are the chief inhabitants of the coast, and the people most conversant with the sea in those parts of the world. In some of its characters it resembles the *Ephippii*, or horse-men, noticed in the article already referred to; but it has a projecting horn above each eye, and a prominent crest on the forehead, with various other characters, which entitle it to be the type of a separate genus of this most singular family. Cuvier has given it the name of *Taurichthys*, which is of course only the Greek for its Malay name of *Ikan-carbauw*, buffalo-fish, or bull-fish.

The remaining principal genera of the scaly-finned fish, exclusive of those that have been hinted at in the former article and in this, which may perhaps be considered as subgenera of *Chatodon*, are as follow—:

BRAMA. These have scales on the vertical fins, and only a few spinous rays in these fins almost wholly concealed under the membrane. They have slender bent teeth placed like those of a card on the jaws, and also on the palatal bones; they have the muzzle very short and blunt, the profile descending rapidly, and the mouth when shut directed upwards, so as to be almost vertical; they have scales on the edges of the jaws, inner gill rays, and their stomach and intestines are rather small, with five coecal appendages to the latter. One species is found in the Mediterranean, and sometimes in the Atlantic, though

only as a stray. It is of considerable size, bright steel blue in the colour, and excellent eating. Very little has been mentioned with regard to its habits; but from the position of the mouth it appears to live under its food, and is in all probability a bottom fish, unless when it comes to the surface or the shallows for seasonal purposes; and, as is the case with eels and various other bottom fishes, it is much infested by intestinal worms. It is held in so much estimation, that, for its size, it is one of the most costly fishes taken in the Mediterranean. According to Risso, it winters in the deep water, where small troops are found assembled together. At these times it is healthy and in excellent flesh; but after it has spawned, which it does on the shores in the summer months, it is sickly and subject to the attacks of the parasites, which take possession of the intestines, and also bury themselves in the flesh. This and some others of the present family have sometimes been described as belonging to the *Sparus* family; but they have the general characters of the scaly-finned family.

PEMPHERIS. The fishes of this genus are found in the Indian seas, and our knowledge of them is exceedingly limited, as it indeed is of most of the curious fishes which are so abundant in that great and fertile expanse of the oceanic waters.

PSETTUS. These are deep and thin fishes, having no inconsiderable resemblance to *Platax*, only the teeth are very small, and set like the pile of velvet; and the ventral fins have only one spine, without any soft rays. They are fishes of a silvery colour, found in the southern ocean, but very little respecting them is known.

PIMPELOPTERUS—Thick Fins. These have teeth of a form different from almost any other fishes. They form only a single row in the jaws, with the front edges sharp and cutting, but have a projecting heel at the posterior side of the base; they have the body oblong, the outline of the muzzle blunt, and the fins scaly and thick—whence their name. They are found in the tropical and southern seas, and have the habit of following ships, in order to catch any thing that is thrown overboard; but they do not bite readily at a bait, and they are not of great value even if they did.

DIPTERODON, are fishes found near the Cape of Good Hope, they have the teeth bevelled off like chisels, and two dorsal fins, the spinous one separated from that with the soft rays by a deep notch.

TOXOTES (Archers). These have the body short and compressed; the dorsal fin on the last half of the back with very strong spines in the anterior portion of it, and the posterior portion scaly; the anal fin is placed nearly opposite to the dorsal one, and agrees with it in character; the muzzle is short and depressed; and the lower jaw projects beyond the upper one; the teeth are short and velvety; but they are abundantly supplied, being found in both jaws, on the anterior part of the vomer, on the palatal and pterygoid bones, and on the tongue; the sub-orbital bones and those of the preoperculum have their lower margins finely toothed; the stomach is wide but short, and there are twelve caecal appendages to the intestine near the pylorus.

There is only one known species *T. jaculator*, the throwing archer, which name it obtains from the ease and certainty with which it knocks down its insect prey with drops of water. Its mouth is not drawn out into a pipe like that of the cheilmon; but it does

not appear to be less dexterous in squirting the water, which it can do with certainty to the distance of three feet or more, and instantly bring down its game to the surface of the water. It is said to be equally successful when the insect is reposing on the herbage or the bank, and when it is on the wing. It is a very amusing little fish, and admits of being kept in a jar of water, where it will shoot the flies presented to it with the same alacrity as when it is at its freedom in the sea. The shores of India, China, and the oriental islands, where vegetation grows close to, or in, the water, are the favourable situations for these curious fish; and they are not timid or suspicious, but will allow one to stand by and see the dexterity of their archery.

Taken altogether, the scaly-finned fishes are a curious race, differing in many respects from any others of the class; but we are too little acquainted with them for being able fully to understand their economy, or trace their connexion with the rest of nature.

SQUILLA (Fabricius). A genus of crustaceous animals, belonging to the order *Stomatopoda*, having the body long and semi-cylindric, somewhat resembling that of a lobster, being arched above and flat beneath, the last segment rounded and spined, or toothed, on its posterior margin; the eyes are placed on very short footstalks, the interior antennæ have three filaments, the exterior single, but covered at the base by a broad scale; the thoracic shield is broad and somewhat depressed; the first pair of legs, or rather leg-like organs, are long and strong, and formed for powerful prehension; the last joint shutting upon the preceding, with strong spines, in the same manner as the fore-leg of one of the *Mantida*; the four following pairs of legs are short, especially the third pair, terminated by a small, flattened, and rounded plate, and a curved apical spine, the three posterior pairs of legs being very slender, the femora being furnished with a long and slender filiform appendage. The species are somewhat numerous. They are chiefly inhabitants of the seas of warm climates, but one or two of the species have occasionally been taken upon our own coasts; some of them are of considerable size, and are employed for food by the inhabitants of the Mediterranean, in the same manner as lobsters. The typical species is the *Squilla* (Cancer) *mantis*, Linnaeus, which is very common in the Mediterranean ocean. It grows to the length of seven inches. The genera *Coronis* and *Gonodactylus* have been separated from *Squilla* by Latreille, upon slight structural modifications.

SQUIRREL (Sciurus). A numerous, very pretty, and highly amusing genus of rodent animals, of small size, which reside and find their food chiefly in trees, and are as much at home there as the handed animals, which they in general beat in the velocity of their motions, while their aspect is as pleasing as that of the monkeys is repulsive. Squirrels are exceedingly numerous as a genus, and their characters at once distinguish them from all the rest of the *Rodentia*, and yet they differ so much from each other, that they admit of division into subgenera or groups, besides their distinction into species.

They are all possessed of clavicles, which enable them to use their fore legs like arms, either in grasping or in conveying substances to the mouth, but in doing so they have to use both legs, as the paws are not sufficiently prehensile for being used as hands.

The character from which they get the name *Sciurus*, which means "shadowing tail," and of which the common term squirrel is merely a corruption, is the form of the tail. This tail is very long, and it is usually covered with very long hair or fur, which diverges into two parts on the under side, something after the manner of the two webs of a feather; and the length is generally sufficient to overshadow the whole body, when the tail is brought forward curving over the back. The gnawing teeth in the lower jaw of the squirrels are very much compressed. The hind feet have five toes, and the fore feet four, but sometimes the inner toe also appears on the fore feet as a simple tubercle; they have four tuberculous teeth on each side of both jaws, and a small one in advance of the rest in each side of the upper jaw, but it falls out at rather an early age. The claws upon their toes are crooked and very sharp-pointed, so that they can take hold of small inequalities of the bark of trees, and the toes have a certain degree of lateral motion, by means of which they can grasp toward the centre of the foot.

They are very agile animals, formed for climbing and leaping; and even when they are in a state of confinement, and abundantly fed, they do not feel at home unless they have in their cage a small mill, or tread-wheel, upon which they can exercise themselves. Their spine is very elastic, and accords well with the ready action of the joints of their limbs, so that they are nearly as nimble on the ground as they are in climbing and scrambling about among the branches. Their action upon the ground is not running but leaping, in which the elasticity of the spine comes into play at every step; and their action is something intermediate between that of the hare and the jerboa, less of a running action than the first, and less of a set of boundings from the hind feet than the second. Their limbs are all articulated, so that they can be stretched outwards, which prevents that steady motion parallel to the mesial plane of the body, which is essential in an animal which has habitually to walk the ground. But while their members are thus not of a walking character, neither do they resemble the flying extremities of the bats, nor the climbing ones either of the handed animals or the sloths. Their feet, both the fore ones and the hind, are fitted for making a firm plant on a very slender branch, either longitudinally or across. This of course is done by a sort of grasping; but still it partakes much more of the character of a mere plant than that of the handed animals, and is performed in a correspondingly shorter time. Their motion along the small twigs near the top of a row of tall trees is thus a kind of running, and running which is very neatly as well as very swiftly performed. Their hind legs are a little longer than their fore, but only a very little longer, as their running style of motion requires that they should have nearly equal command and use of all their legs. In this may be seen the difference between them and the hares and jerboas on the one hand, and the tree apes which have not the tails prehensile on the other. The leaping animal has the hind legs long, and the muscular action of the body very much concentrated upon them. The climbing animal has the fore legs long, and the concentration upon them. The squirrel holds an intermediate place, and this is the reason why we consider its motions on the ground more graceful than the leaping of the jerboa, and its motion in the tree more so than the

climbing of the ape. Their motions are quite a study in animal mechanics; and on account of the lightness, the gentleness, and the cleanliness of the animals, they are a very pleasing study.

The eyes of the squirrels are very large and bright for the size of the animals; and there are some peculiarities in them which are worthy of attention. The pupils are large and rather oval, with the largest diameter placed in a horizontal direction; and there is no colour reflected from the choroid membrane. Hence it is probable that their vision is very keen, and that they can see an object clearly with very little light. They require this, for they have to find their food and also their footing, the latter often very quickly, in the close shade of the leaves. It is probable that their hearing is as acute, for their ears are remarkably well developed, and they often terminate in tufts of fur, which are generally regarded as increasing the acuteness of hearing.

In woods, their chief food is nuts and other small fruits; but they are also fond of the saccharine juices of plants; and it is said that, in some parts of the United States, where they are particularly numerous, they do very serious damage to the plantations of Indian corn, by gnawing the straw at the time when there is sweet juice at the nodes or joints. They are animals of temperate and even of cold countries, as well as of warm ones, though the greater number are found in countries which are rather warm, and they do not occur in the mountain forests of countries near the poles, and are but rare in the lower and warmer places. But they abound so much in many places of the north that they are caught in traps, as well for their flesh as for their skins. The great natural forests are their chief abodes, where they dwell in solitude or in society, according to the species. But even the most solitary of them are usually found in pairs, which pairs are understood to associate for life. Their nests are usually little spherical cabins, formed of twigs near the tops of the highest trees, and with the opening above. In such places they and their young are out of the reach of all quadruped foes; but they occasionally become the prey of ravenous birds, when these roam on the wing over the forest; and yet the situations in which they are placed render them pretty secure from these foes also. Some species, however, form burrows at the roots of the trees. The nests are not accessible, and indeed not easily found out, and so the number of young at a litter is not accurately known; but we may presume that they are pretty numerous; for the females of some of the species have eight mammae, six on the belly and two on the breast.

With the exception of Australia and the remote islands, squirrels of one species or another are found in all parts of the world; in Europe from Lapland to the extreme south; in all parts of Asia, Africa, and North America; and they are as abundant as they are widely distributed, for the woods which suit their economy literally swarm with them. They admit of convenient division into three sections founded on very obvious characters—the absence or the presence of cheek pouches, and the divergence or non-divergence of the fur on the tail, from a mesial line on the under part.

I. Without cheek pouches, and with the hair divergent along the whole length of the tail. These are regarded as the true squirrels; and of them the typical, or at all events the best known, species is

THE COMMON SQUIRREL (*S. vulgaris*). There is perhaps no animal which has stronger claims to being a native of every country of Europe than this one; for, with the exception of the English "squirrel," and the French *ecureuil*, which are both obviously derived from the Greek, it has an original name in almost every part of Europe, at least where any vestige of an original language is retained, which is not a character that can be given either to the English or the French. It may not be amiss to mention one or two of these names, because it will be perceived that, though they differ considerably, there is something very expressive of quickness of motion in the sound of each and all of them. The Gaelic name is *Feoragh*, which means hurry or bustle; the Welch is *Guiwair*; the Germans call it *Eikhorn*, and the Swedes *Ikorn*, which are obviously the same word; the Slavonians and Bohemians, and also the natives of the mountains to the south of the Lower Danube, call it *Wewerka*, which sounds something like the Welch; but the Hungarians call it *Eart*; the tribes near the Ural mountains call it *Ur*, the Finlanders *Arorva*, and the Laplanders *Arre*; the names given by the Asiatic tribes are different from any of these, *Kerma* is the Kalmuc name, *Tyia* the Kirghese, and *Line* the Mongol.

An animal which has so many original names, in countries differing so much from each other as these, and being abundant in them all, must of course have no ordinary facility of adaptation to climate; and accordingly it varies much both in the colour and the thickness of its fur. In France and the south of Germany it has various shades of reddish on the upper part, and white on the under; but the pile of the fur above is red at the points only, and annulated with alternate white and brown in the remaining part. Even there, there is a considerable difference in the colour at different seasons; but when we go farther to the north the difference increases; and in the most northerly forests of Europe, and in those of Siberia, the winter colour is slate grey, with small points of black, the coat being very close and thick, and forming no contemptible fur. The pile of the fur is then annulated with a mouse-grey and light grey alternately. In this state it is more abundant in Siberia than in the north of Europe; and the fur is thicker and of superior quality. It is chiefly obtained in the wild woods on the banks of the Obi and Jenessi; and it is called grey squirrel, or Siberian squirrel in Britain, and *Petit-gris*, little grey, in France; the *Grison*, of which it is the diminutive, being one of the gluttons (*Gulo*), a carnivorous animal, and of course quite different from the nimble and gentle squirrel. There is another change which takes place in the north part of Siberia; in Europe the squirrel is very nearly of the same size, in all its range, and all its variations of colour; but in Siberia it becomes considerably larger. This, however, is no proof whatever of a different species, or of any thing more than a more climatal variety; and that it is only this is proved by the example of the foxes, wealens, and other animals there, which are uniformly of larger size, though the same identical species as those of the north of Europe. According to Pallas, there are squirrels nearly of a black colour in the mountain forests of Daouria, and other places near the lake of Baikal in the south of Siberia eastward; but it is not very clearly ascertained that they are the same species. In Britain the squirrels are not so bright in

the red colour as they are in France and the south of Germany.

Squirrels are provident creatures, and lay up stores of provisions against the winter, consisting of nuts, acorns, beech-mast, the seeds of pines, peas, beans, and all other large seeds which they can collect. These are generally hoarded in some hollow of a tree near the abode of the animal; but there does not appear to be much truth in the common saying, that the squirrels are the great planters of the oak, by the acorns which they bury in the ground, and are afterwards unable to find out; for, when an animal has the instinct of hiding any substance as a supply of food, it has, as a matter of course, the instinct of finding it again; and that a squirrel should range the forest burying acorn after acorn in places where they would be apt to germinate, is very incredible. The store is always in a dry place, where it can be preserved from growing.

There are few matters more tantalising than to attempt watching the motions of a squirrel among the thick branches of lofty trees. Both its eye and its ear are so very sharp, that it generally sees the observers or the pursuers fully as soon as they see it; and then it is "once and away," for one can hardly tell the direction which it takes, and it doubles so nimbly, that while it is looked for in one direction, it is very apt to be off in another. When pushed to extremities it can take very astonishing leaps for so small an animal, for in Europe it is not above seven, or at most eight inches in length, and yet it can leap twice as many feet with great apparent ease. The tail appears to be of great use to it, both in balancing the body while it runs, and in serving as a parachute when it leaps, in doing which it also spreads out the limbs, and so presents the greatest surface possible to the air. Upon such occasions the tail is always curved, reflected forward over the body, in which position the furry side of it is against the fall. When occasion requires, the squirrel can take to the water and swim well, for which it is qualified by the lightness of its body and the breadth of surface which it presents. Some have alleged that it uses the tail as a paddle, or, at all events, as a rudder in swimming; but the character of the organ renders this very unlikely, if not impossible. The probability is that, whether it answers the purpose of a sail or not, it is borne much in the same situation as one, namely, over the back of the animal.

The sitting position of the squirrel is as graceful as its motion is fleet. It rests on the hams with the tail recurved, and in that situation it can bear itself entirely on the hind quarters, so as to have the free use of the fore paws; but if any sight or sound arrest its attention, the tail is lowered, and perhaps that organ may assist it in springing into an active position in case of the necessity of a rapid escape from danger. In the middle of the day squirrels are commonly at rest, but they are active among the branches toward evening. The young are produced about the middle of the summer; and until they gain strength for enabling them to seek their own food, both parents are equally assiduous in bringing them a supply. The squirrels, by the time that their stores are exhausted, are busy little creatures until these are again filled; for, by the time that the young are so far advanced as not to need any farther supply from their parents, the collection for the following winter begins. It is supposed that the young associate in pairs as

soon as they leave their parents, though the fact has not been established, and there is of course no physiological impulse to the association at that early period of their lives ; but as there remains an attachment of the old ones, without any immediate reference to sexual causes, it is probable that the young may possess the same. The squirrel is so neat and orderly an animal, that it is one of those to which there has been a strong disposition to ascribe reasoning powers ; but there is of course not the slightest foundation for such an ascription. That a neat animal should have more reasoning faculty than a clumsy animal, rests on no better foundation than that a regular crystal should have more speculation than an amorphous lump. When the weather begins to get warm in the spring, the squirrels shed their winter coats ; and though the period of their gestation is not known, this appears to be done before the pairing time, so that, with them as with other mammalia, the new fur is the nuptial attire ; but it does not acquire its full beauty till the season is pretty far advanced. It has been said that the squirrel has bred in a state of captivity ; but the fact is a little doubtful, the more so that, had this been the case, the time of gestation would have been observed and mentioned.

When squirrels are introduced into a place favourable for them, and not molested, they increase very fast. A good many years ago they were very numerous in the park at Dalkeith-house, one of the seats of the Duke of Buccleugh. At that time there were all the securities of a city of refuge in that extensive park to every living creature which took up its abode there. Whether the case is not the same now we are ignorant ; but at that time the park was rendered very pleasant, and also highly valuable as a menagerie of British natural history, by the quiet and security in which the animals lived, and their perfect confidence even when one came almost close upon them. The hares might be patted on the back, the birds let you do every thing short of absolutely touching them ; and the squirrels would sit upon not the very high branches of the tall trees by the shady walks, as if they were showing themselves for your special observation. If you passed on perfectly silent, or even conversing with a friend, they would keep their posts without any symptom of apprehension ; but if you gave a loud whistle, or slapped your hands together, they would scamper off a bound or two to a higher pitch, while a dozen more which you had not previously noticed, would be put in motion, all getting higher, but peeping down at you with the most perfect confidence and good nature, as if every one challenged you with "good-bye—catch me now if you can." There are indeed few of our wild mammalia so interesting as squirrels ; and as there is no case of doing any serious mischief made out against them, it would be highly desirable to see them in every wooded park in the country. It is doubtful whether they might not be turned to account in an economical point of view, for although they are small animals, their flesh is remarkably delicate and wholesome. It is true that it might run a little counter to the notions of those that have admired the lively motions of a squirrel, confined and condemned to the tread-mill, to think of killing so very pretty and engaging an animal ; but the feeling is probably much the same with those who are fond of a pet lamb ; and yet lambs are killed by hundreds of thousands, and the most refined and sentimental persons in

the country seek after their flesh with the greatest avidity.

In the plate, *SQUIRRELS* there are graphically represented several species, which afford an illustration of some of the distinctions of the different sections. They are well worthy of attention, and we refer to them thus generally, in order to avoid repeated allusions.

THE ALPINE SQUIRREL (*S. Alpinus Pyrenaicus*.) This species is, as its name imports, found in the upland woods of the Pyrenees ; and it is certainly also to be met with in many other alpine districts of the south of Europe ; but no mention has been made of it as occurring in the north. Mere difference of colour would not of course constitute a difference of species, in an animal so subject to variations of colour as the common squirrel. But to change the tint of a colour, especially in cases where the pile of the coat is annulated, and to find new colours which never break out in any of the known climatal changes, are quite different matters. Besides, there are some differences in form for which no climatal cause can be readily assigned ; the head of the alpine squirrel is smaller than that of the common one, though the size of the body is nearly the same ; the upper part of the alpine squirrel is dark brown, mottled with small dots of yellowish white ; and the under part of the body and inside of the legs are pure white, as are also the borders of the lips ; the outside of the legs is grey, the feet are yellow ; and there is a yellow line upon each side separating the brown of the back from the white of the under part, and the grey of the limbs ; the hairs on the tail, which are long, and divergent in the same way as those on the common squirrel, are black for some distance at the points, and annulated with yellow and black in the rest of their length ; and those at the tip of the tail are wholly black when the tail is seen in profile, with the points of the hairs overlaying each other ; but when seen from above it appears brown ; the colours change with the season, being more black on the upper part in the summer when the fur is young, and more brown in the winter. This is a very common case with alpine mammalia. Cattle and sheep, which have the new covering of the body pure black, and the old one dull reddish-brown, especially at the tips of the pile, are to be met with abundantly on the Scotch mountains. It does not appear that there is any, or, at all events, much difference in the appearance of the alpine squirrel in respect of age ; for those which were kept in the menagerie at Paris, renewed exactly the same colours at every change of their coats, which were changed in the spring in the same manner as those of the common squirrel. No difference of habit is known between the one of these squirrels and the other ; farther than that the alpine one has been met with only in the south of Europe and as a mountaineer, while the other is more abundant in the middle latitudes and the north, and is found in the low and sheltered places rather than in the lofty and exposed ones. It is possible that the squirrels approaching to a black colour, which Pallas mentions as occurring in the south of Siberia, are the same as the alpine squirrel of Europe ; for the colour on the upper part approaches to black during the summer. The black appearance of the tail on the lateral view, and also of the ear tufts and the whiskers would farther agree in favour of the identity of these. Nor is there any

geographical obstacle; for as the more northerly squirrel of Europe ranges into the north of Siberia, so may we expect to find the squirrel of the Alps and the Pyrenees on those mountains of Siberia, which have nearly the same climates; and it is to be borne in mind that the climate of the mountainous part of Siberia, near such an expanse of water as the Lake of Baikal, does not partake of the arid character of those mountains on the same parallel of latitude, which are remote from any considerable expanse of water. There may, however, be very considerable climatal differences of these squirrels as they are found on the mountains of south-eastern Europe and those of north-eastern Asia, even on the supposition that they are the same species; for we have seen that there are great differences in this respect among the squirrels of the north. There is a tendency to grey in the winter months, even when these squirrels are in the alpine woods of Europe; for the tails, which in summer appear as if the blackest parts of them, become greyish in winter. Little is known of them, however; for in addition to the difficulties that there are in the way of attentively studying squirrels in a state of nature any where, there are the additional difficulties of the places which they inhabit.

GREY SQUIRREL OF CAROLINA (*S. Carolinensis*). Buffon confounded the Carolina grey squirrel with the common squirrel in its grey state, under the common name of *petit gris*, and as he has been followed by the compilers, there is in the books no small quantity of error upon this as upon many other points of natural history, where they have arisen from the same source, and been propagated by the same means. Now, if it had been once considered that it is only in high latitudes and during the cold season of the year that the common squirrel is grey; and that Carolina has almost a tropical climate in the summer, and that this squirrel is grey then, it would have shown that there must be a greater difference between the two animals than any that could arise from exposure to climate. There are, however, still greater differences of appearance; the Carolina squirrel is subject to more variations of colour in the same individual, at the same season and in the same place, than the common squirrel is at considerable differences of season and latitude. Sometimes it is whitish-grey; at other times it is much clouded with yellowish, and at other times again the flanks are almost wholly of a yellow colour; so that if there is any resemblance to any known squirrel of the eastern continent, it is to the alpine one and not to the common, at least so far as colour is concerned. In confinement, too, its colour changes very much, which is not the case with the common squirrel. The ears are also without tufts; the long silky hair and the soft wool which compose the fur, are nearly in equal proportions; and the insides of the fore legs are covered with the same kind of hair as the whiskers. It is also, sometimes at least, much larger than the common squirrel, three times the size according to some of the authorities, which has led to the supposition that those very large ones may be a different species from the smaller. In a state of confinement, this species is very active at some times; but it is fond of constructing a round nest of hay or straw in the corner of its cage, in which it lies quietly for great part of the day. The woods of the Carolinas are very extensive and very difficult to explore, so that there may be many va-

rieties, species, and perhaps even genera of wild animals in them, of which, at the present time, we have obtained no knowledge. We should bear in mind how it stood with the natural history of most parts of Europe, when they were as little known in their topography as the wilds of America are at present.

MASKED SQUIRREL (*S. capistratus*). There appear to be at least coloured varieties of this species also. It inhabits the same parts of America as the preceding one, but not the same kind of grounds, being more an animal of the dry and sandy places, of the pine burrows and the maple woods. It is a large animal as compared with the common squirrel, being often two feet in length including the tail, which is rather longer than the body and head taken together. Its colour is usually black, with the ears, the muzzle, the toes, and the tip of the tail white; the black is, however, in the points of the pile only; for the rest is annulated, and, like most annulated hair and fur, it is subject to considerable variations. It is more seen than the squirrels of the richer parts of the woods, and thus it falls a prey to foxes, rattle-snakes, and birds of prey. When discovered in a tree, it seeks to conceal itself by crouching closely to the surface of a branch.

There are many other species or varieties of squirrels in the North American woods, varying from each other in colour and size; but very little is known of their habits farther than as they may vary to suit the animals to all the characters of country, from the sandy height to the perpetual swamp, in which one or other of them is to be met with. It is worthy of remark, however, that the mountain races in North America have often stripes along the flanks parting the upper colour from the under, as is the case in the alpine squirrels of Europe.

On the table land of Mexico, the squirrels are richer in the colour than they are in the United States, and especially than they are in Canada. This is true of all widely distributed animals; their colours are always brighter in proportion as their localities are more tropical; and the squirrels being animals which are very susceptible to the colour of climatal causes, we may be prepared for more remarkable changes of colour in those than in animals which are constitutionally most stubborn and permanent. We shall notice one or two of the Mexican species.

VARIEGATED SQUIRREL (*S. variegatus*). This is the *Quauhtecallil-quapachtli* of the native Mexicans; and its habits differ considerably from those of the squirrels that have been hitherto mentioned. It rarely if ever climbs trees, and never nestles in them, but in holes of the ground, though generally under cover of bushes or the roots of trees. It is an animal about twice the dimensions of the common squirrel of Europe; variegated with black, brown, and red on the upper part, and also on the upper side of the tail, with the exception of a few white markings toward the tip; the under side orange red; and the ears without any tufts. It is likewise probable that this species is also found in some parts of the United States; for a red-bellied squirrel is mentioned as occurring there without ear-tufts, but of much smaller size than this one is described as attaining in Mexico. Indeed, the succession of squirrels from Canada to Mexico is a subject which is worthy of some attention. There seems to be a regular gradation in their appearance, more so than there is in most animals of the same genus inhabiting different parallels through

a large portion of the quadrant. There seem also to be longitudinal differences of these animals in the severe latitude of America; for those which occur on the right bank of the Mississippi are richer in the colour than those that are in the Atlantic side of the country. This we might perhaps be led to expect, as the western country is more dry and also more tropical in all its characters.

THE BLACK SQUIRREL (*S. niger*) is coloured very similarly to the masked squirrel already mentioned, but is not above half the dimensions. Its face is described as being in general black, but with some white markings very differently placed in different individuals. In some the nose is white, in others the feet; in others, again, the tip of the tail; yet, again, there is a white collar round the neck; and these markings may all appear in the same individual, or any number of them may appear in any of the combinations which they can form. These circumstances render the history of the species uncertain; but it appears, if a distinct species, to be pretty widely spread, for it has been obtained in the States and also in Mexico. It is described as being a much more social animal than the grey squirrel of Carolina.

The squirrels of the tropical parts of America, and also those of the extreme north of the States and of Canada, appear to belong to the other section of the genus.

The squirrels of Africa and Asia, especially those of the south-east part of the latter, and of the adjoining isles, are very numerous, and some of them are of much larger dimensions, than the greater part at least of those which we have noticed. The greater number of them, however, have little more history than what is to be found in a museum catalogue, and could not, therefore, afford much interest of a popular kind. We shall, accordingly, restrict ourselves to very short notices of two or three of them, which we shall take in places considerably wide of each other, as this will give the best idea as to how they are diversified, so as to be adapted to the very wide range to which we have alluded.

BARBARY SQUIRREL (*S. getellus*). This is a small species, one-third less in its dimensions than the common squirrel of Europe; that is to say, the total length of the head, body, and tail, is only about nine or ten inches, of which the tail occupies more than one half. It inhabits the woods on the slopes of the mountains of Atlas, and is said to occur also near the south-western deserts in Asia. The upper part of the body is brown, with four longitudinal stripes of white, extending from the shoulder to the base of the tail; the belly is white; the tail reddish ash, mottled with small points of black. Its habits are little known.

MADAGASCAR SQUIRREL (*S. Madagascarensis*). This species is about double the dimensions of the common squirrel. It is deep black on the upper part, yellowish white on the cheeks and under part of the neck, and yellowish brown on the belly; the tail is black, and there are no tufts to the ears; it has the tail very long, considerably exceeding both the body and the head; and in this, as well as in some other particulars, it resembles the squirrels of some parts of the East.

PALM SQUIRREL (*S. palmarum*) is a small species, not much, if at all, exceeding the Barbary squirrel in size, and having a considerable resemblance to that

in some other respects. The hair upon this one is short and rather coarse, and there are no tufts to the ears. The ground colour is reddish brown, mottled with grey, and marked by two or three longitudinal lines of white along each side; the under part is yellowish white; the tail is reddish brown on the upper side, and whitish bordered, and sometimes striped with dusky black on the under. As is the case with many of the others, this species appears to be subject to many varieties of colour, for the stripes are sometimes lighter in the colour than the rest of the upper part, and sometimes darker. They vary in number too, being sometimes five, or a dorsal one and two lateral ones on each side; sometimes three, and occasionally nearly obliterated. The hairs on the sides of the tail are erectile, so that it spreads out in the form of a leaf; but, though it can be raised to a considerable angle with the axis of the body, it cannot be completely removed, as in the common squirrel, and indeed in most of the species. It has been chiefly, if not exclusively, found in western Africa, near the banks of the Senegal and the Gambia, and in the Cape Verd islands. It is a very pretty little animal, and the expansions and contractions of the breadth of the tail, by the erection and pronation of the hair, is curious, though not peculiar to this animal. As to what difference of habit is connected with this peculiarity of the tail, we have no positive information.

THE GINGI SQUIRREL (*S. Gingianus*) is a native of the south of Africa, and, though it has some resemblance to the other African species that we have mentioned, it also differs from them in many respects. The upper part is greyish brown, the hair is pure white on the basal part, and annulated with black and brown towards the tips; it is short and coarse; and on the under part of the body, which is pure white, there is very little hair; the basal part of the tail is nearly the same colour as the back; but the distal part has the hairs white, with the exception of a portion of the middle of the length, which is brown. Specimens of various other squirrels have come into Europe from Africa, and it is by no means unlikely that there are many in the country of which we are ignorant. It is also very probable that African and Asiatic species have been confounded with each other by the dealers at the Cape. When both Java and southern Africa were in the hands of the Dutch, there was no possibility of wholly avoiding blunders of this kind. The dealers at Cape Town got skins in the country from the settlers, and they had them also from Java and the other parts of the East. Sometimes specimens of the one place were most in demand, and sometimes specimens of the other, and the dealer generally named his commodity so as to suit the best market; and, as those about which nobody knew anything were the most prized on account of their novelty, matters went on, and there were no means of detecting the mistake till people began to travel and observe for themselves. In a merely mercantile point of view, there could not be said to be any very great fraud in this mode of proceeding; for the skin of a squirrel is of exactly the same intrinsic value as a commodity, in whatever part of the world the animal may have lived; but in settling the geography of the animal it is a very different matter.

The rich and wooded parts of India, and the Oriental isles, especially the latter, are, however, the

grand head-quarters of the squirrels; and the chief reason seems to be, that fruits are more plentiful in the woods there than in those of any other parts of the world. They are also of more ample dimensions than in almost any other part of the world; but some of them belong to the round-tailed section, and not to the pure squirrels, which have the tail divergent, broad, and shading.

MALABAR SQUIRREL (*S. maximus*). A figure of this species is given in the plate "SQUIRRELS." It is the largest animal of the whole genus, being as large as an ordinary-sized domestic cat. The top of the head, a band along the cheek, the middle of the back, and the flanks, are very bright reddish brown; the shoulders, the rump, and the thighs, are pure black; and the muzzle, the lower part of the neck, the breast, and the belly, the under sides of the hind legs, and nearly the whole of the fore legs, are bright yellow. It is one of the brightest in its colours of all the squirrels, though, like most of the rest, it is subject to considerable variations. It occurs in several of the richly wooded districts of India, but it is said to be most plentiful on the west or Malabar coast, to reside chiefly among the palm trees, and to be particularly fond of the milk of the cocoa nut.

LESCHENAULT'S SQUIRREL (*S. albiceps*). This is a native of the Oriental isles, and called *Jeralang* by the natives of Java. For a squirrel, it is rather a large animal, being more than a foot long in the head and body, and with the tail still longer. The hair on the whole of the body and the legs is close, coarse, and thin, so that the form of the animal is better seen than in the furry squirrels of the cold latitudes. The upper part is dull yellowish grey, the hairs being brown at the bases and yellowish at the tips; the tail, which is very flat and feather-like, though not nearly so broad and bushy as in many of the squirrels, is the same colour on the upper part as the basal portion of the hairs on the back of the animal; the under side of the tail, and also the feet, are brownish yellow; the nape is pale grey, and all the under parts white. The colours of this species, as is the case with most of the others, are subject to great variations, some having the whole of the head and neck, and a portion of the flanks, white, and others being much darker than as above stated.

THE TWO-COLOURED SQUIRREL (*S. bicolor*). This species is found on the mainland of the south-east of Asia, especially in the Malay peninsula, which has so many points of resemblance to the eastern islands, and it is found in those islands themselves. It is still larger than the preceding, being three feet in length, including the tail. It has obtained its name from one instance of the very variable colours which it shows in different individuals. As giving origin to the name, all the upper part, and also the outsides of the legs, are dark coloured, inclining to black, and the under parts are yellow. These colours are far from being generally descriptive of the animal; for the upper part is all shades from almost black to dull yellowish grey, and the under part is of all tints from dark tawny to pale cream-colour. The ears are of moderate size; the head rounder than that of many of the squirrels; and the thumbs on the paws are rudimental, with a little flat nail; the other dimensions of the fore feet, and also the fore toes on the hind feet, have the claws rather strong and very sharp. The great differences of colour which occur in the same species of these animals render the history

of all the large squirrels of the East a matter of no little perplexity. Many persons visiting those eastern countries have named and described species of squirrels; and we have no doubt that any person who goes there, in order to earn the renown of having found a new squirrel, will hardly fail in procuring one different from any that has hitherto appeared in Europe. It would not conduce to any more useful purpose, however, to take note of the almost endless variety of these animals, than it would do to attempt a minute description of all the spots or markings upon a numerous herd of our variegated cattle.

II. Without cheek-pouches, but with the tail round, or having only a small portion at the tip flattened, with the hairs diverging from a mesial line on the under side. These are chiefly, if not wholly, the squirrels of the tropical parts of South America; but they occur also in the East.

GUIANA SQUIRREL (*S. astrans*) resembles the common squirrel of Europe very much in the form of its body, only it is rather larger in size. The upper part is maroon brown, and the under part russet. The tail is of the same colour as the upper part, with clouded rays of yellow, and the tip is black; the whiskers are also black, and so are some long and coarse hairs on the insides of the fore-legs. It is found in palm trees of different kinds, on the fruit of which it in great part subsists; but it is also found upon the ground, where it leaps about with no inconsiderable agility, though the tail does not form so perfect a parachute as in the true squirrels.

SMALL GUIANA SQUIRREL (*S. pusillus*). This is a very little species, the body and head not exceeding three inches in length, and the tail being about the same. It is called the "wood-rat" in Guiana. The upper part is mottled ash colour and yellow; the breast mouse-grey; and the rest of the under part fawn colour. There are no ear tufts, but the insides of the ears are furnished with hairs of the same fawn colour as the body of the animal. The whiskers are black. This is a very pretty little animal. There are several specimens mentioned as occurring in museums, the native countries of which are not known; and it is probable that some of them which are now well ascertained to be natives of the Eastern Archipelago have been set down as inhabiting South America. The oriental ones, which were observed and described while Batavia was in the hands of the British, are much more clearly and satisfactorily made out. Of these we shall notice one or two.

JAVANESE SQUIRREL (*S. insignis*). This animal is called *Bakkal* by the Javese. It is between seven and eight inches long in the body, and nearly the same in the tail. The ground colour is tawny or greyish brown, passing into white on the under part; and a rusty streak extends along each side, all the way from the angle of the mouth to the hinder part of the animal. There are also three well defined stripes of black, about an inch in breadth, each extending from the hind head to the tail, one on the ridge of the back, and one on each side of it, the distance between the stripes being equal to their breadth. The front and muzzle are blackish-grey; and all the under parts white. The feet are of the same blackish-grey as the forehead and the muzzle. The tail is deeper in tint than the body, clouded with brown and black, and slightly interspersed with grey hairs, the hairs being rather long and loose, but not divergent on the under side.

SQUIRRELS.

Flying Squirrel

Malabar Squirrel

Gray Squirrel

Rafflesian Squirrel.

RAPPLES' SQUIRREL. A figure of this is given in the plate. It was discovered on the island of Sincapore; but it is probably found in many other of the adjacent places. It is greyish-brown above, with cross bands; white on the head and the whole of the under part, and with a rusty-brown streak along the side, as in the preceding species; the tail is dark coloured, quite round, rather thicker at the middle than at the origin, and tapering to a point. The hair upon it is loose, but it is not well adapted for acting as a parachute, and there is no enlargement of the skin of the sides to assist in the performing of that operation. The body and head are about nine inches in length, and the tail is an inch or an inch and a half shorter. Little or nothing is known of their habits; but it is supposed that all the round-tailed squirrels are more or less ground animals.

THE SLENDER SQUIRREL (*S. tenuis*) is another species of the oriental isles, first noticed in Dr. Horsfield's interesting account of the animals of that part of the world. It has much resemblance to the preceding species in its general form, but it is much smaller and differently coloured. Altogether the length of it is only about ten inches and a half, of which the tail measures five. The upper part is clouded with black, dark brown, and tawny, passing into tawny on the sides, and into yellowish-grey on the under part. The colours all melt gradually into each other, without any line on the side. The neck and the sides of the head are tawny. The tail is greyish with obscure black bands and minute spots of tan colour; and the single hairs are annulated, tawny at the base, black in the middle, and grey at the points. The tail ends in a long slender brush of a grey colour. It appears that the habits are, partly at least, those of a ground animal; but little is known of them with any thing like certainty.

From the great quantity of food that there is in the forests of the oriental isles, both for tree squirrels and ground ones, it is highly probable that there are many more species in them than have been described; and also that they are very generally distributed. They are, however, subject to so much variation in colour that their history could not be rendered perfect, without more research than can be expected in places so difficult to be explored, so unhealthy in the humid places, and so infested with dangerous animals, and with men hardly less dangerous in some of the inland fastnesses. The early notices of the animals of this portion of the globe are but little to be depended on; and thus it is possible that the gingi squirrel, formerly mentioned, may belong to the present section, and to the eastern isles.

III. Squirrels with cheek-pouches, and the hair on the under side of the tail divergent, from the mesial line for the whole length of that organ.

The squirrels with cheek-pouches are very widely scattered over the world, although they do not inhabit continuously in any one locality. Some are mentioned as inhabiting far north in America, and a very analogous species, if not a mere climatal variety of the same one, occurs in Siberia. In the United States there are several, and some are found in Mexico, though we are not aware of the existence of any in South America. There are, however, some in Africa and in central Asia; and we may be prepared to meet with all sorts of squirrels in the oriental isles. Squirrels of this third section chiefly gather their food upon the ground; and carry it to their young, or to

their hoards in the collecting season, in their cheek-pouches. We must do little else than name a few of the species.

STRIPED SQUIRREL (*S. striatus*). An American and an Asiatic variety of this species have been described; but it is probable that they inhabit a continuous zone in the two continents, from Carolina westward to the central longitudes of Siberia, with only the interruption of the Strait of Behring and the narrow part of the North Pacific. The American variety is a very small animal, not above half the dimensions of the common squirrel of Europe, though resembling it in colour, only there is a yellowish-white band along each flank, bordered at each side with a stripe of black; and there is another black stripe down the ridge of the back. The hairs on the tail are much shorter than those on the other squirrels, so that that organ is but ill adapted for acting as a parachute. The Asiatic variety is described as being rather larger in the body, being about five inches in length, but the tail is only three. The general colour of the upper part is tawny-brown, marked with stripes similar in colour, in number, and in arrangement, to those on the American variety. The shoulders and the fore paws are dull tawny, and so is the rump between the lines. The outsides of the thighs, the hind feet, and the hair of the tail, are bright russet. This variety extends over a very great range of longitude in the north of Asia, indeed over the greater part of Siberia. The species, whether as American or as Asiatic, is intermediate in its habits between the hamsters and the squirrels properly so called. The individuals are rarely, if ever, found climbing trees; they are ground animals, collecting the seeds of various kinds of plants from the surface of the earth, and making use of their cheek-pouches to carry the food to their magazines. They nestle in burrows, which they usually construct under bushes, or the spray at the roots of trees. The burrow generally has two entrances and two chambers, one of which is the dwelling and the other the store; and the spray, whether of bush or of tree, under which they are placed, helps to defend both against the rains. With their collected store in the magazine, they contrive to live tolerably well under the snow, which lies long above their dwellings in the inclement season of the year.

THIRTEEN-LINED SQUIRREL (*S. tridecemlineatus*). This is an American species, about the same size in the body as the American variety of the preceding, and with a tail about three inches in length. The body is very slender, and the muzzle pointed. The colour on the upper part is dark chestnut, with a white line down the middle of the back, formed of little spots nearly confluent with each other. On each side of this line there are three continuous ones, alternating with three rows of spots; and this, with the portions of the ground colour between, make up the thirteen lines, from which the name of the squirrel is derived. This is rather a rare species in North America, the only place in which it has been found; and nothing is known of its habits, though the analogy leads us to conclude that it is a ground squirrel, and not a tree one.

HUDSON'S-BAY SQUIRREL (*S. Hudsonius*). This is one of the most northerly of the American squirrels, and well known to the Esquimaux, who call it *Siksik*. It is rather less than the common squirrel of Europe. Its colours are: reddish-brown on the back and the

head, with the tail the same colour, but margined with black; the whiskers are black, and composed of very long hairs. This species remains in the colder parts of North America, and is not found so far to the south as the preceding species.

In the mountains of Georgia to the west of the Caspian, and also in the provinces of Persia lying immediately to the south of that great inland sea, there have been squirrels described which appear to belong to this section; and there have been others named as inhabiting Abyssinia, various parts of India, and the eastern islands. There are also said to be some analogous ones in the elevated parts of central America, near the Andes; but these are all so uncertain and obscure, that they cannot be rendered interesting as subjects of popular description.

Those which we have enumerated must serve as a specimen of this very generally distributed and very interesting genus of animals. Among all the mammalia, there is scarcely one that can be named which is found in so many places, and places so widely apart from each other; and though, in almost all the species, there are few animals subject to more variations of colour, either in different localities or in the same locality, there are not very many in which the generic characters are preserved more definite and easy to be understood. It adds to the puzzle which hangs over the natural history of Australia, that those animals which are met with in every other country of any considerable extent should not be met with in it. We have them on all sides of it where there is land; and this would lead us to suppose that Australia belongs to another revolution of the globe than those which have produced the other continents.

STACHYS (Linnæus). A genus of undershrubs, and annual and perennial herbs, belonging to *Labiata*. Two or three species are natives of Britain, where they are called hedge-nettles. One or two are greenhouse plants, and a few are admitted into the flower garden; all are easily propagated.

STACKHOUSIA. A natural order, containing only one genus, and of that only one species, viz., the *S. linarifolia*, which is an herb with stipulate leaves, the calyx ventricose and bearing both petals and stamens, the styles lateral, the ovarium lobed, the fruit dry, and the seeds erect. Of the properties of these plants there is at present nothing known. The *S. linarifolia* is a greenhouse plant, thrives in loam and heath mould, and is increased by cuttings.

STADMANNIA (Lambert). A New Holland ornamental tree, belonging to *Sapindaceæ*, and bearing octandrous flowers. It is a scarce plant in our collections.

STAG BEETLE. A large coleopterous insect, being the *Lucanus cervus*. (See *LUCANIDÆ*.)

STAPELIA (Linnæus). A curious genus of succulent plants, from the Cape of Good Hope. Having five stamens they belong to Linnæus's fifth class, but from the manner in which these are united the genus is arranged among the *Asclepiadææ*. Some of the species bear very handsome flowers, but emit a most abominable scent. They are easily propagated by cuttings, laid to dry a few days before planted in dry soil.

STAPHYLEÆ (Linnæus). A genus of deciduous shrubs, belonging to *Celastrineæ*. One of the species is a native of England, and called bladder-nut, from the appearance of the seed-vessel.

STAPHYLINIDÆ (MacLeay). A family of

coleopterous insects, belonging to the section *Pentamera*, and sub-section *Brachelytra* (which see), and corresponding with the tribe *Staphylinides* of Mannerheim. The restricted genus *Staphylinus*, as at present constituted (instead of comprising the whole *Brachelytra*, as in the system of Linnæus), contains only those large-sized species which have their anterior tarsi dilated, the body nearly glabrous, not hairy, the antennæ filiform, with the tip obliquely acute, and the palpi slender, with the last joint thin; typical species, *Staphylinus erythropterus*, a common insect found in dung, being of the length of half to three-quarters of an inch, with red elytra, and the sides of the abdominal segments with golden pile. There are six other species, excluding the *Trichodermæ* of Stephens. (*Staphyl. murinus*, Linn. &c.)

STARLING (*Sturnus*). A genus of birds belonging to the coriiostraf family of Cuvier's great order *Passeres*, and being omnivorous in their feeding, resembling the crows in some particulars, but differing from them in others. The characters of the genus are these: the bill straight, conical, depressed, slightly obtuse, with an angular ridge on the culmen advancing some way upon the forehead; the nostrils near the base and lateral, anal, and half closed by a thick arched membrane; four toes on the feet, three to the front and one to the rear, the claw upon the last hung stronger than that upon any of the others; the tarsi rather stout, and of mean length; the wings long, the first quill little more than rudimental, and the second and third the longest in the wing.

Two species of starling occur in Europe, and in all latitudes and situations in which they occur their habits and manners are nearly the same. They are noisy, and, as one would say, scolding birds, at the same time that they are social birds, and generally found together in flocks more or less numerous. As is the case with some of the crow family, and with others of the harsh voiced birds, they can be taught to articulate; and on this account, as well as on that of their strong coats and their active motions, they are often kept in cages; and they have acquired in this country a sort of poetical celebrity, from Sterne's pathetic account of the captive starling, which kept constantly calling "I can't get out." They are often found on the tops of towers and steeples along with the pigeons, and they occasionally enter the pigeon-houses. They nestle in holes of lonely walls, crannies of rocks, and openings in hollow trees. At the pairing time there are many fierce and particularly noisy battles among the males; and, as is usually the case with all animals, biped or quadruped, that fight battles of gallantry, the female becomes the prize of the victor. The nest is formed externally of straw, then of rather fine vegetable fibres, and internally it is finished off with still finer ones, or with feathers or wool. This nest is a rude structure, as is usual among birds of the family. The eggs are four in number, about the same size as those of the thrush, and of a greenish blue colour. The male alternates with the female in the incubation, and both birds are assiduous in feeding the young, which do not leave the nest till they are fully feathered. The love-song of these birds is not a very agreeable one, being a sort of querulous chirping, kept up incessantly, as if they were dissatisfied. Their note of actual dissatisfaction is even more agreeable, being a shrill and prolonged whistle. But though their

natural voices are thus harsh, and without melody, they are capable of a good deal of cultivation ; for the birds are very sagacious, and by no means so impatient of confinement as the poetical account holds them out to be.

They can be taught to imitate a variety of sounds very unlike those that they utter in a state of nature. This is not peculiar to them, but belongs more or less to all birds that have harsh voices and thick and fleshy tongues. There are, for instance, no birds of which the natural voices are more disagreeable than those of the parrots ; and yet, after they have been properly taught, there are few birds more amusing. It is true that they cannot warble, and neither can the starlings, but they may be taught to whistle airs with great accuracy. To obtain a starling of the best voice, however, it is necessary that it should be taken from the nest at a very early age, for its capacity of imitation is such, that, if it is left for a time in the company of the old birds, it will acquire their harsh notes, and never after be able to leave them off. If taken in time, it can be taught both to whistle and to speak without very much difficulty, but it requires to have its lessons very often repeated. Some attention to its health, and especially to its cleanliness, is also necessary in this young state ; because, though it afterwards becomes rather a hardy bird, it is very delicate in early life. This might be inferred from the length of time that it naturally remains in the nest ; for birds that remain long there are always delicate up to the natural time of their quitting it, however hardy they may be afterwards.

In warm climates starlings are not definite as to the time at which they breed, and even in temperate climates they have usually two broods in the year, although the last one is not so numerous as the first. As is the case with many other birds of the same family, starlings are very serviceable in some situations, and as annoying in others. They feed upon mollusca, larva, and ground insects of various kinds, especially beetles ; and as these last are the great destroyers of the roots of vegetables in the ground, there are few birds, rooks excepted, which are of more service in fields and meadows than the starling. But, on the other hand, they are very annoying in the vine countries in the autumn, where they assemble in great numbers, and commit very serious depredations. As is the case with the crow tribe, the flesh of the starlings is harsh and bitter ; but it is said to improve greatly when they feed upon the grapes, though that is rather a costly way of improving the flesh of so small a bird. The bitterness is said to reside chiefly in the skin and the tongue, so that, when these are removed, the birds are palatable. Starlings are birds of smooth flight, and do not proceed through the air by upward and downward leaps, but glide away with an easy motion. Also, when they are upon the ground, they run with considerable rapidity, but do not leap, as is the case with the thrushes and some others of the nearly allied genera. There are several species of the genus, some of which species are very numerous, and they occur in both continents, but by some writers they have been confounded with other genera of birds. The species with which we are most familiar is

THE COMMON STARLING (*S. vulgaris*). This bird is between eight and nine inches in length, and weighs about three ounces. The bill is nearly an inch and a half long, bluish at the base, yellow at the

tip, and having the gape very much cleft ; the nostrils have an anal projecting border of membrane ; the upper parts are black, but with reflecting glosses, which vary from green to purple, according to the light in which they are seen ; the green is most conspicuous in the coverts of the wings, the lower part of the back, and the rump ; and the feathers on the neck are long, and partially oval-shaped ; each feather on the upper part has a small triangular spot of brownish grey toward its extremity, and these spots are the "stars" from which the name of the bird is derived ; the quills and tail-feathers are blackish, with ash-coloured borders ; and the under coverts of the tail have broad borders of a whitish colour ; the irides are hazel, and the feet brownish flesh colour. The females and the young birds have the under part scattered over with small whitish spots, and they have the light coloured spots on the upper part of larger size than they are upon the mature male birds.

The common starling is not a rare bird in most parts of Europe, and it is partly migratory, partly not. As British birds, they may be considered as rather common, though they are not found in the drier and more upland parts of the country. In the breeding season they are distributed in pairs, and they build their nests in the places and the manner that were alluded to in speaking generally of the genus. In winter, again, they assemble in flocks, and associate freely with all the other birds that flock at that season of the year. At that time they collect upon the low and humid grounds in the vicinity of the marshes, and many of them leave the country. On the continent they are still more migratory, retiring to the south in vast numbers as the cold sets in, and returning again in the summer. When they flock they are generally found in great numbers upon the humid grounds, and they mingle freely with all the other birds that come upon them. They also readily imitate the cries of other birds ; and it is by no means unlikely that their power of doing this is the principal cause which, at first, led to their domestication, or rather confinement, and the teaching of them to articulate words. Many of those that pass the summer in Britain, and other northerly parts of Europe, make their retreat to more southerly climates in the winter, and those that remain flock to peculiar localities. They do not follow the example of rooks, magpies, and various other tribes, by coming upon the cultivated fields, and near to the habitations of men ; they resort to the low and fenny places, where they seek their food by running about on the ground during the day ; and, when night begins to close in, they collect for the night in the rushes, or other tall withered herbage. Before they rest for the night they perform a number of evolutions, flying round and round the place ; but, whether their object in doing so is to ascertain whether there is any enemy there, is not known, although it is very probable. The south of England is the part of the British islands where they are most abundant, and there they are often found in pigeon-houses, the inhabitants of which they meet in the fields, and accompany them home. They have sometimes been accused of eating the eggs of pigeons, but this appears to have no good foundation. At this time they are much more conspicuous than they are during the summer, when they live dispersedly in single pairs, and are so much occupied in the rearing of their broods, that they are but little seen. Their social propensities are, how-

ever, strong at all times ; and, no sooner are their broods able to shift for themselves, than they begin to associate almost indiscriminately with all other birds that may happen to be in the same locality.

Their familiarity, their docility, and, above all, the facility with which they can be made to articulate, appear to have attracted the attention of mankind at a very early period ; and the interest has been kept up in all countries where the passion of bird-fancying is a strong one. The Persian monarchs are said to have employed them in the somewhat singular royal sport of hawking for flies, which they catch in a mode somewhat resembling that of the swallow tribes, only not so elegant. In modern times they are not employed in this way, though many of them are kept for the sake of their voices, and of the little tricks which they learn to play. As already mentioned, they must be taken very young if they are to be of much value either for their song or their articulation ; because if they are allowed to remain in the nest even half the time that they are naturally there, they acquire the chatter for which they are so conspicuous in a state of nature, and cannot get wholly rid of it by any training to which they can be subjected. Being taken so young, the rearing of them is attended with a great deal of trouble. They must be kept upon moss in a little box, and this moss must be changed every day, the most perfect cleanliness being necessary for their health. Delicate animal food is given to them, generally sheep's heart cut into little shreds (so as to resemble the young of the earth-worm, understood to be what their parents first feed them with in the nest) is what is said to suit them best. But after they are a little advanced, they acquire their omnivorous habit, and can eat both animal and vegetable matters, though they always give preference to the former. Their aptness to imitate the sound of words was not unknown to the ancients, for Pliny alludes to the starlings which were trained for the amusement of the young Cæsars, as being capable of articulating both Latin and Greek. They of course have no more knowledge of language than those birds which no art can make to articulate a single syllable ; but there are few birds that can so accurately repeat a long succession of varied sounds. It is mentioned that when M. Gérardin visited his friend, M. Thirel, in Paris, he was agreeably surprised and astonished by hearing a starling articulate a dozen of consecutive sentences, with the same precision as if they had been spoken by some person in the next room ; and when the bell rang for mass, the same bird called to its mistress by name, " Mademoiselle, entendez-vous la messe que l'on sonne ? Prenez votre livre, et revenez vite donner à manger à votre polisson : "—Miss, don't you hear the bell ring to mass ? Take your book, and return quickly to feed your little wag. The same bird whistled various airs in a clear and agreeable manner, and with the most perfect musical accuracy. In Britain the starling is but little regarded, except as an object of curiosity ; and in that respect its interest is not great, as the time of the people is, generally speaking, too much occupied for their devoting much of it to the educating of birds. On the continent it is somewhat different, and in the fenny places there the birds are also sought after as articles of food. They are particularly abundant in Holland ; and, as they fly crowded, and wheel and return again and again to the same spot, numbers of them may be shot with very little labour on the part of the fowler.

The starling is found in all parts of Europe, and also occasionally in Northern Africa. There appear to be some varieties if not different species, for there is one mentioned as being found in Sardinia, which is of a black colour without any spots ; and even the common ones which are found in the same flock are remarkable for the different tints of their general plumage.

In the north and east of Asia there are some which are probably entitled to rank as different species. Among these may be mentioned the Daourian starling (*S. Daourica*), which is considerably smaller than the starling of Europe, being only six inches in length. The upper part of the male is black with purple reflections, and whitish margins to the quills ; and the under part whitish-ash colour ; there is a white stripe on each side of the head ; and the bill and feet are lead colour. Another species, the green starling (*S. viridis*), is common in China. It is green on the upper part, without any spots ; has the quills with white shafts and margins ; a small crest of black feathers on the top of the head ; and the bill and feet reddish. Another species of the eastern continent has been called the Cape starling (*S. Capensis*), though it appears to be a native of India, rather than of Southern Africa. Its general colour is blackish on the upper part, and white on the under, with the neck and throat deep black, though with reflections of purple ; there is a small spot of reddish-white upon each cheek, and a band of the same colour on the back of the neck, and a small red spot between the eye and the nostril ; the bill is yellow at the base and black toward the tip ; and the feet are yellow with black claws.

An Australian bird (*Creadion pharoides*), is sometimes classed with the starlings as the carunculated starling (*S. carunculatus*), from two orange-coloured wattles, each almost a quarter of an inch long, which are pendent, one from each angle of the gape. The upper part of it is rusty black, and the rest of the plumage pure black ; the bill is blue at the base, and black at the tip, which last is also the colour of the feet ; it is about an inch longer than the common starling of Europe. There are various other varieties named as occurring in different parts of the eastern continent ; but they are in all probability only climatal ; and it has been remarked, that the warmer the climate in which they are found, the deeper are the colours, and the richer the reflected tints of the plumage.

The Louisiana Starling (*S. collaris*), was described by Gmelin as the great lark. It is a bird about nine or ten inches in length. It is not confined to the part of America from which it is named ; for it also occurs in the United States and in Canada, but moves southward in the winter, and collects in vast numbers on the humid plains on the banks of the Lower Mississippi. It is indeed more exclusively a marsh or meadow bird than the starling of Europe, and confines itself to the open grounds near the rivers, never perching on trees, as is the case with the starling of Europe. They are much more numerous in the central states of America in autumn than they are at any other season of the year, as they then collect from the north and flock ; whereas, in the breeding time, they live much more dispersedly. They are swift of foot, and nimble and ready on the wing. When observed they take flight, but speedily squat down in the cover of the bushes and tufts. They do

not associate in such numerous flocks as the starlings of Europe, though there are often many of them on the same meadow. They have all more or less of a social disposition toward each other, and also for the other birds that resort to the same places; but there is a closer attachment between the members of small parties which keep together and have their movements in concert, and they appear to be the family of the year. After they separate in pairs in the spring, the male and female show a great deal of attachment for each other, and both are very attached and attentive to the young ones. Their nests are placed in the cover of bushes, and the eggs vary from five to seven in number. There is understood to be only one brood in the year.

The colour on the upper part is much mottled and broken by various spots and markings of black, brown, red, and grey; there is a whitish stripe down the middle of the back of the neck, and a shorter and less conspicuous one upon each side, which passes over the eye; the cheeks are grey; the quills blackish, with grey borders, and marked with shades of brown across; over the eyes and on the throat, the colour is yellow; but there are black mustachios, and a patch of black upon the breast; the lower part is yellowish with dusky blackish spots, which are most numerous on the lower part of the breast toward the great black spot; the under sides of the wings are yellow; and the under part of the tail is reddish with cross bars of brown; the bill is brown above and ash-coloured below, and the feet are grey; the length is nine or ten inches.

SOUTH AMERICAN STARLING (*S. militaris*). In the summer, which answers in point of time to our winter, this bird is found as far to the south as the Falkland Isles and the Straits of Magellan; but at other times it ranges nearer the equator, although we believe not further to the north than the lower valley of La Plata. It is rather smaller than the starling of North America, and different in its colours; and it is also more of a vegetable feeder, coming in flocks upon the cultivated grounds and eating the grain. The upper part is brown with yellowish margins to the feathers, and the under part is crimson, mottled with black upon the flanks; the scapular feathers are red, and the quills and tail-feathers black; each side of the head is marked with a white stripe from the gape to the hinder part of the head; the tail is forked; the bill and feet are brown; the females and young are paler in the colours.

Like the starlings of North America, these are ground birds, frequenting the open places, nestling in tufts and bushes, and never taking up their abode in the holes of rocks, or perching upon trees. They have many of the characters of the starlings of the eastern continent, and yet it is doubtful whether they ought not to be formed into a separate genus or subgenus.

Various other starlings have been named and described by authors, chiefly from museum specimens, the differences of which are only those of colour. This is, in a great measure, the case with the green one, which is said to be Chinese, and there is a liver-coloured one reported to be also of China, which stands in the same predicament. Considered in themselves they are not very interesting birds; and they are so scattered about, and so roaming in their dispositions, that they are not very characteristic.

STATICE (Linnæus). A genus of perennial

herbs, mostly natives of the north of Europe. The genus belongs to *Plumbaginææ*, and some of the species are called sea-lavender, and used as edgings to flower borders.

STELLARIA (Linnæus). Annual and perennial herbs, mostly natives of Europe, and belonging to *Caryophyllææ*. Several species are found in Britain, where they are called stitchwort.

STENIDÆ (MacLeay). A family of coleopterous insects, belonging to the sub-section *Brachelytra* (which see), corresponding with Mannerheim's tribe *Stenides*. The typical genus *Stenus* (Latreille) is distinguished by the large size of the eyes, the length of the sub-cylindric body, the tarsi distinctly five-jointed, and the very great length of the retractile labium. Stephens describes nearly seventy species, all of which are of small size, frequenting damp situations, as the margins of rivers, ponds, &c., especially in grassy and sandy places. They are generally of a black colour, but a few are ornamented with a red spot on each elytron. The typical species is *S. cicindeloides*, so named from the analogy which it exhibits with the *Cicindela*, in the great size of the eyes.

STENOCHILUS (Dr. R. Brown). A genus of evergreen shrubs, natives of New Holland. The flowers are didynamous, and the genus belongs to *Myoporinææ*.

STERCULIA (Linnæus). A genus of fine ornamental trees and shrubs, chiefly natives of South-eastern Asia; the flowers are monœcious, and the plants belong to *Byttneriaceææ*. The species are very various in appearance and character, and are easily kept and propagated in our stoves or greenhouses. The *S. platensis* is almost hardy; several specimens, in different parts of England, having survived two or three severe winters.

STERNA (Tern). A numerous and rather interesting genus of web-footed birds, which career over the marshes and waters much in the same style as the swallows do over the land, on which account they are sometimes called sea-swallows. They are birds of light weight, but clean and firmly made, with very long and pointed wings and forked tails; and the freedom and rapidity of their motions give no small interest to the waters they frequent.

Their general characters as a genus are: the bill as long as the head or longer, straight, compressed, grooved at the sides, and sharp and cutting at the tip; but there are some species in which it approaches in form to that of the gulls. The mandibles are of equal length, and the upper one is bent for some distance near the tip, against which the point of the under one acts as in the petrels, and other birds which gather their food on the wing over the sea. They in fact take up the pasture of the margin of the waters, where the gulls leave it, as these are met by the petrels which are still farther to seaward. The nostrils are near the middle of the length of the bill, and pierced through and through. The feet are short and weak, and naked of feathers to some distance above the tarsal joints. The three front toes are webbed with a notched membrane, and the hind one is free, and the claws are small and crooked. The birds can walk, and they can also swim; but neither of these is their principal motion, or that upon which they depend in the search of their food. The wings are always very long, extending beyond the tail when closed, and the first quill is the longest. The tail is

Z Z

more or less forked. Indeed, were it not that they are water-birds and the swallows are land ones, they resemble these in very many particulars. Their voices even have some resemblance to those of the swallows, by sharp hissing screeches.

The style in which the terns twitch down to seize the small fishes and fry that are near the surface of the water is often very splendid; and one knows not whether most to admire, their rapidity of flight or their facility of descent, just to tip the surface of the water, and instantly again to ascend and be on the wing. How they can see with such unerring certainty, and change their motion so instantaneously from the forward rush of the wing to an absolutely perpendicular descent, as if it were a stone or piece of lead falling, is a matter which we cannot very well explain or even understand; but that they do it is certain, and as vision is the only sense that they can have to guide them, their powers in this respect must be wonderful. Taking them in the average of their species, they are not so much sea-birds as they are birds of the marshes near the sea, and the lower parts of the valleys of the great rivers that are occasionally flooded. Some of them are found upon the inland waters, or at all events upon the land-locked seas, and the rivers that flow into these. In the spring they come to the shores in considerable bands; but they generally disperse themselves in single pairs in the breeding season. In winter they are more upon the flooded grounds.

The birds are so rapid in their motions, and the habits of some of them are so little known, that it is not possible to give a general account of their manners that is sufficiently clear. In respect of their habits they might perhaps admit of division into four sections, though there are no structural differences sufficiently marked for giving these much interest in a systematic arrangement. The first of these divisions might include the species which, especially in the breeding season, find their food chiefly by fishing in the inland waters, and thus keep near the margins. A second division are more discursive over the surface of those waters, and their food is less known. A third division breed in the marshes, and live upon insects, spiders, and other little creatures which they capture when on the wing, as well as upon fish. The fourth division are more of sea birds, and deposit their eggs on the sands and flats, and especially on the small islets near the shores and in the estuaries of the rivers. Those of the last division are the characteristic ones of the British islands; for our inland waters are not ample enough, or the lower parts of our rivers sufficiently flooded, to afford scope for the others. The countries which lie toward the Black Sea and the Caspian, and the marshy banks of the rivers that fall into those seas, especially the Danube, are the great haunts of the terns on the eastern continent; but there are also many on the American marshes. The fact is, that their wings are so ready and so powerful, that a flight of a few hundred miles is with them a matter of but small effort. The haunts of the marsh ones are both difficult and disagreeable to explore, so that we are not so well acquainted with their habits as it would be desirable to be with those of birds of so much energy of character. But our notice of them must be brief, and we must in a great measure confine it to those which are generally or occasionally found in the British islands, or upon their shores,

THE GULL-BILLED TERN (*S. Anglica*). The epithet *Anglica*, or English, is very inappropriately applied to this one, inasmuch as it is really not an English bird, and occurs in our part of the world only as a very rare straggler. The proper habitat is the east of Europe, especially the marshes of Hungary, and the countries below that on the Danube; but it ranges considerably both to the eastward and the westward; and seasonally it is found by the marshy or flooded places near the rivers that fall into the Caspian and the lake of Aral. This tern of the central marshes of the eastern continent is a much more heavy bird, and slower in its motions, than the terns with which we are more familiar on our own shores; and in its general make, as well as in the form of its bill, it has no slight resemblance to those gulls which breed in the marshes. Indeed there is one of the gulls which inhabits nearly the same locality; and probably the two perform the office of scavengers together. It is not a little curious that, though this species is by no means rare in the east of Europe, the first notice of it by naturalists should have been by the late Colonel Montagu, from a specimen found in England; and thus its introduction to natural history is English, though the bird itself is really a foreigner.

This tern is a bird of considerable size, and well winged, though, as we have said, rather a heavy flyer. The extent of the wings from tip to tip is about thirty-four inches, or half a foot more than double the length of the body. The bill is very strong and of a dark colour, and has a projecting angle at the middle of the lower mandible the same as in the gulls, and the tip is also formed in a similar manner. From the similarity in form there is every reason to infer a similarity of office, and that the tern is alternately a fisher and a scavenger as circumstances may require. In the summer plumage the head and neck are black, and the upper parts greyish white, with the shafts of the quills and tail-feathers pure white. A streak from the gape to the eye, and all the under part of the body, are also white. In winter the head and neck become nearly white; but the black is restored in the spring moult. The tail is forked, and the closed wings extend at least two inches beyond the tip of it. The nest is formed in a tuft or bush by the side of the marsh from which the bird procures its food, or on a hummock within the marsh, if there happens to be one adapted for the purpose. The nest is constructed wholly of dry vegetable fibres, and the eggs are four in number, of a greenish-olive colour, and marked with brown spots.

THE CASPIAN TERN (*S. Caspia*) is another species of the central marshes of the eastern continent, and, as its name implies, a more easterly inhabitant than the other marsh tern. On the Caspian it is very abundant; and, though one of the large and heavy terns, it sometimes, although not very frequently, straggles into England, the place where it is most likely to visit being the east coast of Norfolk.

In its summer plumage the upper parts of this species, with the exception of the head and neck, are ash colour, and the under parts white. The head and neck are deep black, the feathers on the latter being long and silky. In winter it is supposed that the black fades as it does in the preceding species; but the habits and the breeding place of this one are little known. It is in the winter plumage that a few specimens of this bird have straggled into England. In that state the front and part of the head are white,

while all the rest of the upper part is bluish ash, with the exception of the wing-coverts, which are brownish with cross bars of black and white. The quills of the wings and all the under parts of the body are, at this season, pure white; the feet are black, and the bill is vermilion red. Whether these are the winter colours which the birds uniformly assume in those places where they are numerous and native, has not been ascertained; but it is probable that they are. When full-grown, there is not understood to be much difference in the appearance of the sexes, either in the summer or the winter; but the young birds have those parts which are ash-coloured in the adults mottled with black.

THE SANDWICH TERN (*S. Boysii*). This is a species of the principal habitat of which there is not much known, the chief notice that we have of it being as rather a rare bird on the south-east coasts of England, though it is probable that it breeds there, not, however, in any considerable numbers. It is a bird of a foot and a half in length, and about two feet nine inches in the extent of the wings from tip to tip. The back and the coverts of the wings are grey; the principal quills have the shafts and inner webs white, and the outer webs mottled with small dots of black. The top of the head, as far down on the sides as the eyes, and backward to the nape, is black. The under parts are white, with a blush of rosy colour on the fore-neck and breast, which vanishes in the winter, at which time the head also becomes more or less mottled with white, or white altogether.

This species is usually found upon marshy places near the sea, and it is particularly abundant in Holland, and along the low shores of Germany. Its chief subsistence is small fishes, which it captures with great ease and readiness while driving about on the wing. It is not found at any distance inland, or far out at sea.

THE LESSER TERN (*S. minuta*). This bird is very generally distributed over the temperate and the cold parts of the northern hemisphere; but in the eastern continent and in America, the long dreary beaches of sand or shingle are the places over which it is usually found; and it adds considerably to the interest of places that have not very much to recommend them, by the rapidity of its movements and the plaintive wailings of its voice. It is between eight and nine inches in length, and more than a foot and a half in the stretch of the wings. The upper parts of the body, the wings, and the tail, are pale grey; the quills of the wings being a darker shade of the same colour. The top of the head, the hind head, and a streak from the gape to the eye, are black, and the forehead and all the under parts of the body pure white. The young birds are, however, very differently coloured from the adults, so that they are liable to be mistaken for another species. The head is then mottled with black and grey; the back with grey and yellowish white. The tail in the young state is very little forked.

These birds remain on the beaches all the year round, though they are more scattered in line in the winter, and collect into parties, on the grounds best adapted for their breeding, in the summer. The breeding time, for it cannot be called a nesting time with them, is during the warmest time of the year. The eggs are placed on the bare ground among the pebbles of the shingle, and it is probable that the heat of the sun during the day assists in hatching

them; for, even where there are a considerable number of birds careering about on the wing, it is very rare indeed that a female is started from her eggs, and thus the birds afford no clue to such as seek for them. During the night, however, it is understood that the female sits, and that she sits also during the day in case of rain. The eggs are only two, or at most three, and they are placed in a little depression of the sand or small gravel; they are pale brown, and spotted over with dusky and ash-coloured blotches.

Though this tern is far from rare on the sandy and shingly margins of the sea, and also of the great inland lakes of the eastern continent, it has nowhere been so closely observed or so faithfully described as by Wilson. It arrives, that is, collects upon the spots favourable for breeding, on the coast of the American States, about the end of April. It "coasts along the shores, and also over the pools in the salt marshes, in search of prawns, of which it is particularly fond; hovers, suspended in the air for a few moments above its prey, exactly in the same manner as some of our small hawks, and dashes headlong down into the water, generally seizing it with its bill, mounts instantly to the same height, and moves slowly along as before, eagerly examining the surface below.—About the 25th of May, or the beginning of June, the female begins to lay. The eggs are dropped on the dry and warm sand, the heat of which, during the day, is fully sufficient for the purpose of incubation. The heat is sometimes so great that one can scarcely bear the hand in it for a few minutes without inconvenience. The wonder would therefore be the greater should the bird sit on her eggs during the day, when her warmth is altogether unnecessary and perhaps injurious, than that she should cover them only during the damps of night and in wet and stormy weather."

From this Wilson draws the conclusion which almost any one would have drawn at the time when he wrote, namely, "that the actions of birds are not the effect of mere blind impulse, but of volition, regulated by reason, depending on various incidental circumstances, to which their parental cares are ever awake." Now that this tern is not guided by anything that we call an impulse, either blind or not blind, is perfectly true. A blind impulse is an attempt to proceed in ignorance in a matter where knowledge is absolutely necessary, while an impulse which is not blind, or, as we may call it, a rational impulse, is one in which the party proceeds upon a well-established ground of experience. The bird cannot proceed in either of these ways; for that which cannot acquire experimental knowledge can never be said to be ignorant, for we are ignorant of nothing which is not knowable, or to the right performance of which experience would not be a certain guide if we were in possession of that experience; but the bird has no need of experience. The young bird which never saw an egg, performs her incubation in exactly the same manner, and as perfectly free from mistake or error, as the mother of a dozen of broods; and it would be just as vain to speak about an ignorant bird blundering in its incubation, as to speak about an ignorant stone forgetting the way to fall after it were half way down the pit or the precipice. It is much to be regretted that even the very best books on the natural history of animals are vitiated by the frequent occurrence of this false philosophy, which instils the very worst of errors often with the best intentions.

Though there is no impulse on the part of the tern to this incubating only during the night and when the weather is inclement, yet there is an obvious purpose answered by it in nature, and this is the proper lesson of wisdom for us to draw from it. Where the tern breeds the pasture is rather a poor one, and food, even for a small bird, cannot be obtained without a good deal of labour. From the smallness of the prey too, and the necessity of ranging for it on the wing only, the clearest light is essential for the feeding of the bird; and those very circumstances of the locality which render it necessary that the female tern should be abroad finding her food for the greater part of the day, carry on the incubation of her eggs without her assistance at the time, when she is thus occupied.

Thus, when we take a proper view of this, we come to the very same conclusion to which we are led in every case in nature when we take it upon its own evidence, and do not call in the aid of a gratuitous sort of "inferior reason," which vitiates the whole case. All the birds of bare and sandy places, from the ostrich on the great inland desert to the tern on the shingly beach of the sea, are under the same law, though that law, as well as their own organisations and habits, are varied so beautifully according to the circumstances, that each is the best adapted for its own locality. If the bird must, according to its general habits and habitation, range the whole day in feeding, the eggs are always so placed as to be hatched by the sun during that time; but to give the bird credit for plan and purpose in this matter would not be less absurd than to give it credit for plan and purpose for having adapted the structure of its body to the place which it holds in creation. Indeed, if we admit the one we eventually admit the other, whether we avow it in so many words or not.

Wilson says that the eggs of the lesser tern in America are generally four in number, while the most careful of the British authorities say that they are never more than three. This would not be a ground for supposing a difference of species, because the eggs of various birds are more numerous in America than they are in the corresponding species of Europe. This seems to arise from America being better adapted for the bird. In the tern this is remarkably the case, because there are many more salt marshes and mud banks on the coasts of America than on those of Europe. These eggs are very similar in size, shape, and colour, to those that occur in this country, and they are always placed higher than the greatest high-water line. We must not consider, however, that the bird studies their safety any more than that she places them on the dry surface, *knowing* that the sun will assist in hatching them there. The birds are very clamorous, however, when their breeding-ground is invaded. Wilson says—"During my whole stay, these birds flew in crowds around me, and often within a few yards of my head, squeaking like so many young pigs, which their voice strikingly resembles. A humming bird, that had accidentally strayed to the place, appeared suddenly among this outrageous group, several of whom darted eagerly at him; but he shot like an arrow from them, directing his flight straight toward the ocean." The food of these birds is exclusively animal—insects, crustacea, small mollusca, and all the produce of the peculiar places to which they resort. They feed on the wing, catching their prey

in the air, on the ground, or in the water; but they do not walk in search of it. They can range for a long time, but they are often much exhausted, and remain motionless on the ground for hours together. Besides having more numerous broods, the American species is about an inch longer than that of the eastern continent.

AMERICAN MARSH TERN (*S. aranea*). This species is about the same size as the gull-billed tern of the eastern marshes, but it is a bird of different character, more rapid on the wing, and with the bill differently formed. The length of this species is fourteen inches, and the stretch of the wings not less than two feet ten inches; the bill is rather stout, much rounded on the culmen, and of a glossy black colour; the crown and nape are black, and the rest of the upper part dull bluish white, with the shafts of the quills and tail-feathers pure white; the under parts are pure white; the tail is much forked, and the closed wings extend two inches beyond it; the legs and feet are black; the eggs are three or four in number, of a greenish olive colour, spotted with brown; the young have the points of the feathers on the upper part of the head white, but the basal parts, as far as the black extends in the mature birds, is dark coloured; the feet are dusky orange, and there are some mottlings on the tips and edges of the primary quills.

Wilson found this species on the cold marshes, where the eggs were deposited on the drift grass without any formal nest. The principal food appeared to be a large black spider, which is abundant in these situations, and moves under the water as well as in the air.

THE BLACK TERN (*S. nigra*) occurs in Britain, but it is not a very common bird. Its breeding-places are by the pools in the salt marshes, and the nest is placed in the cover of reeds and other tall aquatic herbage. It makes a nest, though a very rude one, of dry leaves and other vegetable matters. In its dimensions it exceeds the lesser tern, though not by a very great deal. In summer the upper part of the body is bluish-ash, with the exception of a small margin of white on the external feathers of the tail; and the nape, the chin, the throat, and all the under parts, are greyish-back. The male is easily distinguished at this season by a small white spot on the chin, which is wanting in the female. In winter all the colours of the under part fade to white, and the colour on the back becomes much paler in the tint. The webs of the feet are much more deeply notched between the toes than those of the other terns. The young have the upper part brown, with the borders of the feathers paler than the rest. During the breeding season these birds keep close in the cover of the marsh vegetation; but in the end of summer, when their broods are matured, they disperse along the line of the shores, the time of their stay in the marshes being about three months. They have been sometimes confounded with the common tern, but they are a distinct species.

THE ROSEATE TERN (*S. dougalii*). This is a larger species than the preceding, and its habits are less those of a marsh bird, for it is found only by the sea, and in the lower estuaries of the tidal rivers, especially where there are flat islets and long expanses of shingle and sand, without being flooded at high water. It is fifteen inches in length, but has the wings much shorter in proportion than most of the

others. The upper part is grey, with black or dusky on the webs of some of the quills, but with all the shafts white; the head and nape are black, and all the under parts white, with a rosy tint on the neck, the breast, and the middle of the belly. The geography of this bird is not very well known, but it is supposed to be a bird of the colder latitudes. On the shores of many parts of the Baltic, and also on those of Denmark and Norway, it is said not to be uncommon. In Britain it is rather a rare bird, and has been usually seen in company with the common tern.

THE COMMON TERN (*S. hirundo*). This is the species which is best known, and the one which has, by way of eminence, got the name of sea-swallow. In the mature bird the upper part is pure ash-colour, the cap on the crown of the head and nape black, and all the rest white; the feet and basal part of the bill are red, and the tip of the bill black. The length is about a foot. The young have the plumage on the upper part mottled, and the chin, which is white in the old birds, of a dusky colour; the colour of the tip of the bill varies in different individuals, and the plumage changes with the season, and partially also with the latitude. There is also a considerable seasonal movement in the birds. They resort to much more northerly places in the breeding times, and more southward, again, in the winter; and, as they are found in different dresses in the two localities, they have been by some multiplied into several species. They are very widely distributed over most shores abutting on the north Atlantic; and they are found in abundance upon all parts of the British shores that are adapted to their habits. They leave the high rocks to the gulls, petrels, and other birds, which, ranging over the surface of the water, have also much more of a swimming habit than the terns. But on the low shores, where there is an accumulation of sand and shingle, and the bottom is for a considerable way alternately exposed and covered, there is sure to be abundance of them; and their rapid motions on the wing, and the shrilly cries which they utter, all tend to give them that peculiar character which imparts so much interest to the sea-birds, especially in lonely places. They deposit their eggs on the bare sand. On the British shores these are seldom more than two in number; but on the shores of America they are generally three—another proof that it is more favourable for beach and marsh birds than the eastern shores of the Atlantic. The eggs, as is frequent with sea-birds, are larger in proportion, of a dim yellow colour, and mottled with spots of brown and dusky. The common terns depend more upon the waters for their food than most others of the genus, for they live in great part upon the fry of fishes, which they are very expert at twitching out of the shallow water. During the day the eggs are left by both birds, unless in case of rain; but they are far from abandoning them. The birds are never at any great distance from the eggs; and the instant that any one approaches the place, they are in a state of great excitement, and, by their squeaking and wheeling about in the air, endeavour to draw the attention of the visiter, and keep up their motions and their voice around him, until they have got him to a considerable distance. Indeed, if one walks along for some distance where the beach is favourable for them, he may have a guard of terns the whole way; for one pair hand over the traveller

to another, and he continues to get well scolded until he is fairly out of the domain of the terns.

The young, when they break the shell, are not so immediately fit for finding their own food as the young of many other sea birds. A running bird, and even a swimming one, requires little or no attention from its parents, as the one can almost immediately run about, and the other take to the water; but the development of wings upon which the bird shall be borne when it is feeding is another matter; and no bird, as it comes out of the shell, is capable of flight. Therefore, the terns have to be fed by the parent birds until their own wings are fit for flight; and, as young birds are voracious in proportion to the feathers that they have to produce, the terns have a good deal of labour in feeding the young, although the brood is so small. There is a sort of progress in this feeding. While the birds are very young, the old ones divide the food for them, and put it into their bills. After they have grown a little, they twitch it into the mouth of the young, without pausing, on the wing; and when they are nearly fledged, the old ones simply drop the food for them, and leave them to pick it up while they go in quest of more. Soon after this the young are able to rise on the wing, and find their own food, and then the labours of the old birds are at an end for the season. Thus we find that there is no deviation from the general law of nature even here. Every thing in nature, as well as in art, is a production; and the law is general, that the labour which the production demands is in proportion to the value of that production. A wing is a far more nice instrument than a walking or swimming foot; and when it is required as a principal organ in any bird, the parents of that bird must undergo a more severe and more protracted labour.

The very same principle holds in human labour; for, if there is to be additional value in any thing, there must be additional labour in the making or production of it. This is true not only of those fictitious grounds upon which things are often valued, but also upon the score of absolute intrinsic worth. There are circumstances which render the cases not quite parallel. For instance, there are different degrees of knowledge and dexterity in human workers, and these so far affect the results of their labours, that the actual time and labour which the producer expends upon it are not measures of the intrinsic value of a human production. But in nature there is no difference of knowledge and dexterity in the producer, all being alike, and everywhere perfect; and therefore natural productions are entirely free from the uncertain and indeterminate element which affects the productions of human labour. This being the case, the operation—for we cannot properly call it labour—and the production, are always in exact proportion to each other; and this is the ultimate standard of perfection to which the labour of man should be made to approximate as nearly as possible, although it is one which, in the nature of things, never can be reached. When we say that any one production of nature has a certain degree of value or perfection which another does not possess, we only state, in other words, that a greater number of opposing causes have been overcome in the production of it; and as, in nature as well as in art, the only means of overcoming is by the greater being made to act upon the less, the producing energies must be

more exerted in proportion as they overcome a greater opposition. This case of the wings of birds is quite in point, and it is a perfectly general one. It is one, too, which conveys a great deal of useful information, by teaching us that there is "no royal road" to the accomplishment of anything; but that the best and the only way to make sure of success is to make ourselves acquainted with all the difficulties and the means by which they may be overcome. There is no retreat in which we can lay so sure a foundation for knowledge of this kind as the school of nature, and there is no department of nature more instructive or more pleasing in this respect than the birds, especially those birds which have their place and office in nature clearly marked out, and are energetic and open to our observation in their working.

The terns are, in an especial manner, birds of this instructive character. Their place in nature is a very peculiar one, and their labours are exceedingly severe. They are also admirably shaped and organised for this labour. Their bodies are of the very best form for rapid motion in the air. Their strength and weight are concentrated in the wings; and as the feet have a very secondary function to perform, they are small, and the muscles attached to them are very feeble. The plumage of the terns is remarkable for the compactness of its structure and the smoothness of its surface; and it is less disordered by wind or rain, or by collision with solids, than that of most birds. Their muscular fibres, too, are remarkably tough and strong, and they are but little loaded with fat, or with superfluous matter of any kind. These circumstances render them of comparatively little value to man as food—indeed, we may say of no value, for there is little flesh upon the birds, and the little that there is, is of a very unpalatable nature.

Thus formed, they are sent forth to find their food in places where no other bird, or other vertebrated animal, could by possibility live. Even in those places which they frequent there is, however, a surplus of the production of life, and that surplus requires regulation as well as the surplus of the most fertile places. Thus, when we look upon it with anything like understanding, there is really as much perfection in the adaptation of the tern to the barren strand as in that of the ox to the meadow.

STERNBERGIA (Kitabel). A genus of bulbs, belonging to *Amaryllidæ*, natives of the South of Europe. They do very well on warm borders in this country.

STERNOXI (Latreille). A sectional name given to the two serricorn coleopterous families *Buprestidæ* and *Elateridæ*, in consequence of their both agreeing in possessing a more or less acute and produced point at the posterior part of the prosternum, which in the latter family is employed as an instrument for enabling the insects to recover their ordinary position when laid upon their backs. In the *Buprestidæ* this point is broader, and is not employed in this manner.

STEVIA (Cavanille). A genus of Mexican perennial herbs, belonging to *Compositæ*. The species are nearly hardy, but liable to be destroyed by severe frost.

STILLINGIA (Linnæus). A genus of herbs, shrubs, and trees, natives of North America and India. The flowers are monœcious, and the plants belong to *Euphorbiacæ*. In the greenhouse, the species if potted in light rich soil thrive well, and are easily propagated by cuttings.

STIPA (Linnæus). A genus belonging to the *Graminææ*, commonly called feather-grass, and admitted into flower gardens as ornamental.

STOCK. A well known flower-garden favourite, the *Mathiola incana* of Dr. R. Brown. There are many cultivated varieties, as the ten-week, which is an annual, the Brompton, &c., all highly prized for the beauty and fragrance of their flowers.

STEBE (Linnæus). A genus of undershrubs from the Cape of Good Hope, belonging to *Compositæ*. The species thrive in any light rich soil, and may be propagated by cuttings, but are plants of no great beauty.

STOMAPODA (Latreille). An order of malacostracous podophthalmous *Crustacea*, of small extent but very singular structure, which both, as regards the variations of organisation itself, and the curious analogies clearly exhibited with other and distant tribes of animals, renders this a very interesting group. The branchiæ are not affixed at the sides of the thorax, and placed in a particular cavity prepared for them, as in the crabs and lobsters, but where there exists particular organs of respiration, they are found under the form of membranous ciliæ, attached to the sub-abdominal appendages. These animals have the teguments slender and transparent, and not of that firm consistence which is found in the lobster. The carapax or shell is often divided into two parts, one bearing the eyes and antennæ, the other the appendages of the mouth and the thoracic legs; in other groups it is formed of a single piece, and exposes a certain number of the terminal thoracic segments; the abdomen is in general very much developed, and always composed of seven joints; the eyes are affixed upon movable footstalks, the internal antennæ are always terminated by two or three filaments, the organs of the mouth are formed nearly as in the *Decapoda* (lobsters, &c.), but the foot-jaws have the form of large claw-like legs, those of the second pair (or first pair of leg-like organs) very often much larger than the other legs, and used in prehension; the two legs of the first pair have the same form as the foot-jaws, the others are either filiform and furnished with a lateral appendage or rudimental; each of the five basal abdominal segments is provided with a pair of false swimming-legs, like those of the *Macrura*, the sixth segment having on each side an appendage terminated by two plates, forming, with the seventh abdominal segment, an apparatus for swimming.

These crustacea are essentially marine, and die as soon as they are taken out of the water; they are generally natives of tropical seas, not extending beyond the temperate zones. Their economy is not yet ascertained, but it is evident that those which are provided with claws (*Squilla*) employ them in seizing their prey, in the same manner as the orthopterous insects forming the genus *Mantis*. These species generally frequent very deep water, but others, destitute of swimming apparatus, and the body very broad and slender, are generally found at the surface of the ocean, where they float about with very little individual motion.

There are two sections, or rather families, in this order, named *Unipeltata* and *Bipeltata*, having respectively for their types the genera *Squilla* and *Phyllosoma* (which see).

STOMOXYS (Geoffroy). A genus of dipterous insects, generally placed in the family *Conopidæ*, but more properly in that of *Muscidæ*, having the pro-

boevis porrected, elbowed near the base, and very slender, its point being advanced in repose as well as in action; the antennæ obtuse at the tips, with a terminal seta, hairy above; abdomen four-jointed, with the balancers covered by a double alulet. These are small flies which frequent the windows of our apartments in damp summer or autumn weather, greatly resembling the common house-fly, but being of a rather broader shape, and at once distinguished by the porrected proboscis, with which they inflict severe wounds, especially upon our legs, which they seem to prefer, their proboscis penetrating through our clothes without difficulty. They are also found in the fields or woods; and from the circumstance of their being most abundant in autumn, it has been a common saying amongst persons not aware of the difference of species, that the house-flies sting in the autumn. The type of the genus (of which there are several species), is the *Conops calcitrans* of Linnæus. Other species are named, *St. stimularis*, *irritans*, and *pungens*, from their irritating powers.

STRATIOMIDÆ (Leach). A family of dipterous insects, belonging to the division *Brachocera*, Macquart (see *DIPTERA*), having the antennæ apparently three-jointed; but the third joint, on examination, is found to consist, exclusive of the terminal style or bristle, of five articulations; this style or bristle is found in nearly all the species. The wings are laid upon each other in a horizontal position when at rest, with a small central cell from which several indistinct nerves radiate to the posterior margin of the wing; the scutellum is often spined, the legs simple, and the rostrum small. These are generally inactive flies, found in damp situations, but occasionally handsomely variegated in their colours. The genera are *Stratiomys*, *Odontomyia*, *Ephippium*, *Ozycera*, *Nemotelus*, *Chrysoclora*, *Sargus*, and *Pachygaster* (Vapio, Latreille), together with several others recently described by M. Macquart in the *Suites à Buffon*. The typical genus *Stratiomys* is distinguished by having the antennæ much longer than the head, the basal joint long, and the terminal joints forming a fusiform mass; the front of the head is not produced into a rostrum, the antennæ inserted on the forehead, and the scutellum spined.

Figures representing the transformations of *Stratiomys* *Chamaeleon* will be found in the article *INSECT* (vol. ii., p. 840, figs. 38, 39, 40), fig. 38 representing the larva, in which the three terminal segments of the body are much elongated and very slender, and terminated by a considerable number of feathered filaments arranged in a star. The head is small, oblong, and scaly, with a number of minute curved hooks and other instruments, which serve to create a disturbance in the water in which these larvæ reside. Respiration is effected in this larva by rising to the surface of the water head downwards, its star-like apparatus at the extremity of the body being extended to the surface, and having the effect of repelling the fluid. In this manner the insect remains suspended for a certain time, an orifice situated at the base of the filaments giving passage to the entrance of the air; but when it is desirous of descending it has the power of bringing the extremity of these filaments together, enclosing at the same time a bubble of air which it carries down to the bottom for its future use, and which appears like a globule of liquid silver. This larva does not shed its skin, but the pupa state is assumed within this covering, which

becomes hard and rigid, the tail often, but accidentally, being at an angle with the rest of the body. They now float on the surface of the water, the pupa occupying one extremity of the old envelope, out of which the perfect insect makes its escape by making a slit at the second segment; it then stations itself for a short time on its old case, its body hardens, and it attains a full perfection. There are six British species of this genus.

The characters and habits of the *Sargus* are given in the article upon that genus; the other genera do not present any characters of interest suited for a work like the present. The British species of this family are described by Mr. Duncan in a recent number of the *Magazine of Zoology and Botany*.

STRATIOTIS (Linnæus). A genus of only one species, viz., *S. aliodes*, a native of Britain, found in ditches. It belongs to the natural aquatic order *Hydrocharidaceæ*.

STRAVADIUM (Jussieu). A genus of tropical ornamental trees, named *Eugenia* by Linnæus, and *Barringtonia* by Roxburgh. They are natives of Malaya; the flowers are monadelphous, and belong to the natural order *Myrtaceæ*. Our imported plants thrive in rich loam and moor-earth, and are propagated by cuttings.

STRELITZIA (Hort. Kewensis). A fine genus of herbaceous perennials, natives of South Africa, belonging to the natural order *Musaceæ*. The *S. augusta* is a favourite stove plant, and also flowers in the greenhouse with good management. It is increased by suckers, and sometimes by seeds.

STREPSIPTERA (Kirby; RHIPIDOPTERA, Latreille; RHIPIDOPTERA, Lamarck). An order of winged insects established by Mr. Kirby for the reception of a few insects of the most singular form and remarkable habits. The name of the order is derived from the Greek, and is in allusion to curious appendages of small size which at first were regarded as attached to the fore legs, and consequently as these legs are prothoracic, and true fore wings are mesothoracic, it was considered by Latreille that the former could not be analogous to wings, and accordingly that Mr. Kirby's name of the order was inappropriate, in lieu of which the name *Rhipiptera* was proposed in allusion to the fan-like form of the real wings, which are very large; in shape like the quadrant of a circle, and furnished with a few longitudinal nerves arranged like the ribs of a fan. Subsequent discoveries have, however, proved that the small twisted organs are in reality mesothoracic, and consequently as truly representations of the fore wings of butterflies, &c., as the elytra of beetles; in some of which latter (*Atractocerus*, *Sitarus*, &c.), these organs are nearly as much reduced in size as the pseudelytra of the *Strepsiptera*. The head of these insects is transverse with large exposed eyes placed on footstalks, divided into a small number of facets; the mouth is of a singular character, there being scarcely any appearance of aperture; there are also two slender and pointed organs inserted widely apart, but crossing each other, and a pair of large two-jointed palpi; the antennæ are very extraordinary in their forms, being generally furnished with an internal branch nearly as long as the antenna itself; the prothorax and mesothorax are very short, forming only two narrow rings, to each of which on the underside a pair of legs is attached; the mesothorax is very greatly developed and divided by several oblique sutures; the legs are

short, slender, and compressed, with the tarsi furnished with fleshy cushions, but destitute of claws; the two anterior pair of legs are close together, and the posterior pair very far behind. The abdomen is small and scarcely coriaceous; it is cylindric, eight or nine-jointed, and furnished with a recurved point.

These insects are of small size, and in the larva state they are parasitic in the bodies of various species of wild bees (*Andrenidæ*), and wasps (*Vespidæ*). The order was first detected by Rossi, an Italian entomologist, who discovered its habits, and formed a genus for the reception of the species which he discovered (*Xenos vesparum*, Rossi; *Xenos Rossii*, Kirby), but he regarded it as belonging to the order *Hymenoptera*. Mr. Kirby having discovered another species belonging to the same group, but to a distinct genus in this country, and having received another species from Professor Peck of America, investigated the subject very minutely, and detailed the characters of the order and its genera in an elaborate Memoir published in the Linnæan Transactions. The following is Mr. Kirby's account of his discovery of the English species, and as it is illustrative of the habits of the insect, we shall quote it at length. Having observed upon various species of *Andrena* "something that I took to be a kind of acarus, which appeared to be immovably fixed just at the inosculation of the dorsal segments of the abdomen, and at length finding three or four upon a specimen of *Melitta* (*Andrena*) *nigroænea*, I determined not to lose the opportunity of taking one off to examine and describe; but what was my astonishment, when upon my attempting to disengage it with a pin, I drew forth from the body of the bee a white fleshy larva a quarter of an inch in length, the head of which I had mistaken for an acarus! After I had examined one specimen, I attempted to extract a second, and the reader may imagine how greatly my astonishment was increased, when, after I had drawn it out but a little way, I saw its skin burst, and a head as black as ink, with large staring eyes and antennæ consisting of two branches, break forth and move itself briskly from side to side. It looked like a little imp of darkness just emerged from the infernal regions. My eagerness to set free from its confinement this extraordinary animal may be easily conjectured. Indeed, I was impatient to become better acquainted with so singular a creature. When it was completely disengaged, and I had secured it from making its escape, I set myself to examine it as accurately as possible, and I found, after careful enquiry, that I had got a nondescript, whose very class [order] seemed dubious." Monograph. Apum Angl. ii., 113.

Mr. Dale, who has been very successful in the discovery of insects of this order, communicated the following observations to Mr. Curtis, by whom they were published in the British Entomology, fol. 226, together with a beautiful illustration of *Stylops Dalii* (fig. A, natural size; B, magnified; C, the andrena with the heads of two of the larvæ exposed between the segments of the abdomen; D, larva extracted and magnified), a species named after the gentleman above mentioned, and whose remarks are as follows:—

"Every specimen of *Andrena barbilabris*, I have seen this year [1828?], from the 27th April to the 4th June, have contained larvæ, pupæ, or exuvæ of *Stylops*, from one to three in each. On the 5th May, I picked out one with a pin; on the 7th another rather immature, and caught one flying in the hot

sunshine over a quickset hedge in the garden; it looked milk white on the wing, with a jet black body, and totally unlike any thing else; it flew with an undulating or vacillating motion amongst the young shoots, and I could not catch it till it settled on one,

when it ran up and down, its wings in motion and making a considerable buzz or hum nearly as loud as a *Sesia*; it twisted about its rather long tail, and turned it up like a *Staphylinus*. I put it under a glass and placed it in the sun; it became quite furious in its confinement, and never ceased running about for two hours. The elytra or processes were kept in quick vibration as well as the wings; it buzzed against the sides of the glass with its head touching it, and tumbled about on its back. By putting two bees (*Andrena labialis*) under a glass in the sun, two *Stylops* were produced; the bees seemed uneasy and went up towards them, but evidently with caution as if to fight, and moving their antennæ towards them retreated. I once thought the bee attempted to seize it; but the oddest thing was to see the *Stylops* get on the body of the bee and ride about, the latter using every effort to throw his rider. A large hole is left in the tail of the bee where the *Stylops* escapes, which closes up after a time. I have found five species of *Andrena* infested. When off the bee the *Stylops* kept its wings still and half erect."

From the recorded observations of Jurine, it is evident that the pupa state of these insects corresponds with that of many *Diptera* in being coarctate, that is, enclosed in the skin of the larva; it also appears probable that it is not until the larva is full-grown, that it protrudes its head out of the body and between the abdominal rings of the bee; but there are still many questions relative to the natural history of these singular creatures, which still remain uncertain. Some curious speculations naturally arise from the remarkable fact observed by Mr. Pickering, of which the details are published in the last part of the Transactions of the Entomological Society, and by whom an *Andrena* was found in the winged state in its cell under ground at the end of the month of December (which had evidently only recently quitted the pupa state), and from the abdomen of which he extracted a perfect species of *Stylops* (*S. Spencii*), as well as a specimen of the larva. The following queries are suggested by Mr. Pickering as embracing

points in the economy of the *Strepsiptera*, respecting which information or confirmation is required.

1. What are the sexual distinctions in these insects?

2. In what manner and at what period of the year does the fecundation of the female take place?

3. At what period of the year are the eggs deposited?

4. Are they deposited separately in the cell of the wasp or bee, or are they laid in the eggs of those insects, or within the larva, pupa, or perfect insect?

5. How long do they remain unhatched, and do they lie in that state until the larva of the insect attacked has attained its full-growth, or assumed the pupa state?

6. How long do the larvæ of the *Strepsiptera* remain in that state? Do they cast their skins? In what manner do they feed?

7. How long do they remain in the pupa state?

8. Do these parasites render abortive the female *Hymenoptera*, in the bodies of which they are reared?

9. Do the sexes appear simultaneously?

10. Do the perfect *Strepsiptera* take any nourishment?

11. Of what use are those acute organs, termed mandibles and the two-jointed palpi?

12. What genera of bees are attacked in this country?

This order consists at present of only four genera, but it is not at all improbable, that when the minute insects of other countries have been carefully collected, others equally interesting will be discovered; indeed, North America and the island of Mauritius have already furnished species of the order.

The genus *Xenos* is distinguished by having both the branches of the antennæ inarticulate. It comprises two species, one found in Europe infesting the body of the *Polistes Gallica* (one of the social wasps), and the other *Xenos Peckii* above noticed.

In the genus *Stylops* the outer branch of the antennæ is flattened and tri-articulate. This genus comprises several British species, and appears confined to the genus *Andrena*.

The genus *Elenchus* has the antennæ similarly jointed, but very long and slender, and the eyes scarcely pedunculated. Type *Stylops tenuicornis* of Kirby. *Elenchus Templetoni* Westw. was discovered at the Mauritius by Mr. Templeton.

The genus *Halictophagus*, so named from being supposed to be parasitic upon the genus of bees *Halictus*, has the antennæ internally furnished with four branches. A single individual of *H. Curtisi* was taken by Mr. Dale near Lulworth Cove, Dorsetshire, by brushing long coarse grass and thistles into a net.

STREPSILAS—Turnstone. A very interesting genus of shore birds, belonging to the longirostral family of Cuvier's *Echassiers*. They have a habit different from that of any other birds which are met with on the shores, numerous and varied as the inhabitants and visitants of them are. In the arrangement of Linnaeus they were classed along with various other birds in the genus *Tringa* (see *TRINGA*); but they have very properly been made a distinct genus by more recent naturalists.

The generic characters are: the bill of mean length, in the form of a lengthened cone, bent at the point, straight in the greater part of its length, but very slightly turned up at the point; very strong, with the crest flattened, and the point truncated; the nostrils

lateral, pierced longitudinally near the base of the bill, and half closed by a membrane; the feet of mean length, naked a little way above the tarsal joints, with three toes to the front and one to the rear, the front ones united at their bases by a very short membrane, and the hind one articulated upon the tarsus higher up than the others; the wings pointed, the first quill being the longest.

The principal habit of these birds which distinguishes them from all their neighbours on the beaches, is that after which they are named, and which is a very expressive one, for they literally turn over stones, when the tide is back, for the sake of the small animals that lurk under them. But they are not confined to the turning over of stones, but turn sea-sand, and all other substances below which the small animals of the beach hide themselves, if their strength is able to perform the task. They do not bore in the sludge as is the case with the longer and more flexible-billed members of the family, neither does it appear that they range the beaches to fish up little animals that are at large upon the surface, as is done by the *Tringas* and some of the others, with which the turnstones were formerly associated in the same genus. They "stick to their vocation," and although their labour appears to be more severe than that of many of their neighbours, they are specially adapted for it, and so they perform it. They are one of the most striking instances we have of the endless resources which are displayed in the animal kingdom, accomplished too by very simple means. There is nothing strikingly remarkable in the bill of the turnstone. It is a slant bill, without being in the least heavy or loaded; it is strongly set on the rounded outline of the head; the point is very hard, and the basal point a little flexible; and it has a bend upwards, so slight that it is just barely perceptible. All these little circumstances, which one who knew nothing of the habits of the bird, would be apt to pass over as indicating little or nothing, appear, however, to produce the very best form of a bill for turning over the pebbles on the beach, and seizing whatever may be disclosed by the operation. We say that this is the best form of a bill for the labour for which it is intended, and we may say so with the utmost confidence, because it is the one which Nature has made for the purpose, and it is unique, as there is only one species of turnstone. We are therefore constrained to admit that this must be the very best form of an instrument for turning stones; that is, the one that can accomplish the work with the least exertion of muscular energy; and, therefore, if we could fully understand the mechanism and the working of this bill, we should have a solution of a problem of no small practical utility in some of the mechanical arts.

As we have said, there is only one known species of turnstone, and this one is scattered over the shores of very many parts of the world, but not in great numbers any where, and only on particular spots. The dry shingle where the turnstones have their nests, and also the oozy and sludgy places where the pebbles are partially imbedded in the mud, are avoided by the turnstone, a beach where the ground equally has some consistency, but not such as to remain very wet, with little stones scattered about, is what this bird chooses; and as it does not invade the pasture of any other bird, so there is not any that invades its pasture, even although other birds

should feed within a very short distance of it. There are few birds so widely and so thinly scattered as the turnstones, and few that preserve nearly the same identical appearance and character in all the localities in which they are found. The raven is almost the only other one which is so perfectly a cosmopolite, and the same and equally at home in every part of the world in which it is found. It is also a very ranging bird, and perhaps there is hardly a locality in which it is resident the whole year round, nor are there any where it makes its appearance as a mere straggler at a distance from the ground for which it is best adapted.

THE COLLARED TURNSTONE (*S. collaris*) is the only known species of this bird, though on account of the difference between the plumage of the old and the young, and also of the seasonal changes, that one has been sometimes described as two. It is a bird of about eight inches and a half or nine inches in length, with the tail rather short and a little rounded, and the points of the wings when closed reaching beyond it. In its plumage it is rather a handsome bird; the upper parts are bright maroon-red, irregularly clouded over with huge black spots; the top of the head is reddish-white, streaked with black; the forehead, cheeks, a large collar, part of the back, the middle of the breast, and the under parts are pure white; a black band passes over the front before the eyes, and divides into two parts, one of which extends to the gape and the other down the side of the neck, becoming broader as it descends, and forming a large gorget on the lower neck and breast; there is a large band of brown on the rump; the external margins of the tail are white; the feet yellowish-orange, and the bill black. The colours of the female are nearly the same in their distribution, but they are paler in the tint. The young of the first year are very differently marked, being without even a trace of black or red; the upper parts are dark brown, with margins of pale yellowish to the feathers; the head and neck are dull ash-colour, streaked with black; the sides of the head and neck grey, mottled with white; the throat and foreneck whitish; the sides of the breasts brown, with white margins to the feathers; and the rest of the under part white, with the exception of a broad band of brown on the vent-feathers; the bill is blackish, and the feet are reddish-yellow. The full plumage of maturity is not acquired till the birds are two years old; and those of a year old are also different from the young; they have the collar and breast-plate blackish, with white margins to the feathers; the cheeks whitish, dotted with black; the top of the head deep brown, with black spots; and the back mottled with black, and reddish; there is also a large white spot upon each side of the tail.

One need not wonder that a bird which varies so much in its plumage, should have its history a little confused; and the confusion is evinced by the fact that the movements of it at the different seasons, even (regarding it as a British bird) are very imperfectly understood. In places near the south it appears only in the winter; but it departs later and comes earlier than many of our migrant birds; so that it is not absent above two or three of the very hottest months of the year. That the birds which remain till the summer has begun are the same individuals that return before it closes is not very likely; but still, the lingering delay and the early visiting are so unlike what happens in most birds, that they ren-

der it probable that some of the turnstones at least may breed in the country, although in what part of it is not known. In the northern islands it is still more puzzling; for a few stragglers remain there all the summer through, and yet the nest has not been found there. They breed on the rocky islands which are so numerous on the coast of Norway; and probably as far to the north as there is a trench clear of ice to be found. They are birds of excellent wing, and powerful muscles, and thus they are capable of making a long journey in a single flight; but what their actual rate and style of migratory motion, in the distances to which they actually migrate, are, we have no means of ascertaining. They appear in little troops, but the migrations appear to be performed in pairs; and when even hundreds migrate in this manner, they are not readily observed. From their limited numbers, and the late period to which they remain, and the early one at which they again appear, it is by no means improbable that some of them breed on the wilds, near those shores upon which they are seen at so short a time both before and after the breeding season. That their nests have not been met with is no conclusive evidence against their being there; for there are parallel cases in the dotterels and some of the snipes; the former of which must breed in thousands upon some parts of our wild uplands; and yet a single one is rarely seen on the breeding ground, or during the breeding season. But their history wants a good deal of investigation before we can speak positively concerning it.

North America is a country far better adapted to the habits of the turnstone than any part of Europe; and accordingly the bird is much more common there than it is with us. It is more of a regular migrant in America than in Europe; and there are facilities for this in the situation of the country. A bird can pass between the extreme north and the tropical regions upon a line of almost unbroken beach, the greater part of which abounds in rich pastures for those birds. Thus the turnstone can proceed by very easy stages, feeding as it proceeds, and not requiring to be stationary at any time, except the breeding season. They winter in the southern parts, visit the middle states in April, and remain there two months, and then remove farther to the north where they breed, returning to the middle states about October, and leaving them for the south when the cold weather sets in. The movements of the turnstone on the American coasts are thus very easily traced; but they depend of course upon the character of the seasons there, which are not the same as the seasons in Europe. In other respects there is, however, but little difference between the birds in the two continents, in size, in colour, or in any other respect. They are subject to the same changes with age and with the seasons, and similar in all parts of their economy. The situation of the nest is not fully ascertained, as it has not been often enough seen for that purpose. The eggs are said to be placed in a very rude nest on the ground, to be in general four in number, olive in the ground, with brown spots. It is probable that they vary in colour, which is often the case with the eggs of birds that are subject to variations.

When the turnstones fly, they utter a querulous sort of twittering note. They also often run about with the wings half opened, and serving as balances to the body; but they do not run so swiftly as the

tringas, and some other birds of the family which find their food by ranging about over the surface, and not by turning over the pebbles. These birds are in motion on their feet for the greater part of their time, and do not readily take the wing. The turnstones again will often remain at the same spot for a considerable time, stirring about the small pebbles with the greatest assiduity. When they shift their ground from one stony patch to another, they generally use the wing; and thus they are more ready to take the wing in case of alarm, than most of their neighbours.

STREPTOPUS (Michaux). A genus of very pretty herbaceous perennials, natives of Europe and North America. The flowers are hexandrous, and the plants belong to *Smilacæ*. The species affect a light sandy soil, and are increased by division of the root, or by seeds.

STROPHANTHUS (De Candolle). A genus of curious evergreen shrubs, natives of China and Sierra Leone. The flowers are pentandrous, and the genus belongs to *Apocynæ*. These plants do well with the ordinary stove management.

STRUMARIA (Jacquin). A genus of Cape bulbous plants, belonging to *Amaryllidæ*. These bulbs require to be planted in light sandy heath mould, and watered only when growing.

STRUTHIOLA (Linnæus). A genus of slender growing shrubs, natives of the Cape of Good Hope. The flowers are tetrandrous, and the genus belongs to *Thymelææ*. The different species do well in the greenhouse, affect light peat-earthly soil, and are propagated by cuttings.

STRYCHNÆ. A small but remarkable natural order of tropical trees, containing three genera, viz., *Theophrasta*, *Strychnos*, and *Fragræa*. They are allied to *Apocynæ*, and several of them are frightfully poisonous. The *S. nux vomica*, or ratsbane, is well known; it is not only fatal if introduced into the stomach, but equally so if injected into an open wound. The inflorescence of the order is terminal, solitary or aggregate, racemose or paniculate, the flowers regular, symmetrical, and united; the calyx is free, persistent, and five-cleft; the corolla below the germen, deciduous, five-cleft, and often with appendages in the throat, and contorted; the stamens are definite, five, rarely more or less, and seated on the corolla, alternating, with its segments equal to them in number, and opposite the lobes of the calyx; the filaments are mostly free in one subtype the *Apocynidæ*, and mostly connate in the *Stapelidæ*; anthers two-celled, pollen granulate, the styles two, and stigma simple. The species of the several genera in our collections, especially the *Theophrastas*, are fine showy plants, and succeed well with the ordinary stove treatment. Cuttings not divested of their leaves strike root readily in sand.

STUARTIA (Cavanille). A deciduous tree, native of Virginia, bearing handsome monadelphous flowers, and belonging to *Ternstræmiacæ*. This plant is frequent in shrubberies, and is increased by layers in peat-earth.

STYLIDÆ. A natural order, containing as yet only one genus, viz., *Stylidium*, a native of New Holland, of which there are several species, either herbs or half shrubby plants. "They have pink-coloured flowers, ornamented with glittering glands; their stamens are united in a column, which is terminated by a sessile stigma, and which is irritable in

so high a degree, that if touched by a pin, it instantly starts from its place with great elasticity." They are propagated by seeds or cuttings, and require a moor-earthly soil. The leaves are alternate, simple, and entire, and without stipules; the inflorescence is terminal, and either solitary, spicate, or racemose; the tube of the calyx is attached to the germen, three-parted, bilobate or regular, and persistent; the corolla is synpetalous, with the limb variously cleft; the stamens are two filaments united with the style; the anthers one or two celled; the style in one with the filaments, and the stigma, which is simple or bifid, is enclosed by the anthers.

STYLOPS (Kirby). See *STREPSIPTERA*.

STYLOSANTHES (Swartz). A genus of herbs and under shrubs, natives of South America, having monadelphous flowers, and belonging to *Leguminosæ*. The species require a light loamy soil, and are propagated by cuttings.

STYPHELIA (Dr. R. Brown). A genus of evergreen shrubs from New South Wales, belonging to *Epacridæ*. They are favourite greenhouse plants, and succeed with the ordinary treatment of plants from the same quarter.

STYPTANDRA (Dr. R. Brown). A genus of herbaceous perennials, natives of New Holland, belonging to the sixth class of Linnæan botany, and to the natural order *Asphodeliæ*. These plants are nearly hardy enough to bear our winter if planted in a warm border, and allowed a little covering in hard frosts.

STYRACINÆ. A natural order containing only two, but rather remarkable genera, viz., *Styrax* and *Halesia*. The species, of which there are seven, are elegant trees with white flowers, natives of North America. The *S. officinale* affords the useful gum imported into this country from Turkey; and in this country the *Styrax* arrives at a tree-like size, and is one of the most odoriferous of plants, especially after rain. The *Halesia* is the well-known snowdrop-tree, a hardy inmate of our shrubberies. They are increased by layers.

SUNDEW, is *Drosera rotundifolia* of Linnæus, a British plant found in bogs. The flowers are pentandrous, and the genus gives a title to a natural order, namely, *Droseracæ*.

SUS—The hog, or rather perhaps *Suidæ*, the hog family. A genus or group of pachydermatous mammalia, differing much, in most of their characters, from all the rest of that very singular class; they have cloven feet, or only two fully developed toes, the same as the greater part of the ruminating animals, and they are the only pachydermata that are miscellaneous in their feeding, the others being exclusively vegetable, and subsisting chiefly upon strong and harsh vegetation, though most of them prefer more delicate food if they can obtain it. The hogs are also chiefly vegetable in their feeding, but they prefer succulent vegetables, especially wild fruits and roots, though, when other food fails, they can subsist upon almost any kind of garbage.

The common characters of the group, which are, of course, most descriptive of the hogs properly so called, as being the typical and by far the most important division, are as follows:—Four or six cutting teeth in the upper jaw, and always six in the under; two canines in each jaw, and twenty-four or twenty-eight cheek teeth in all; the lower incisors are pointed obliquely upward and forward, and the upper ones are conical, so that this part of the mouth is

better adapted for tearing than for cutting; the cheek teeth are different in their character, none of them are grinders, but the ones toward the front are partially trenchant, and those toward the rear are more tuberculous; the canines, which are large in the males only, continue growing during the whole life of the animal, but they can scarcely be in any way regarded as feeding instruments; they grow outwards and upwards, and in the old animals, in which they acquire much size and strength, they curve backwards at the points, and are very formidable weapons, both on account of their uneven size and form, and of the force and determination with which the animal can use them; the muzzle is lengthened into a snout, which has a slight cartilaginous enlargement at the end, is supported by a peculiar bone, capable of some motion, and very abundantly supplied with nerves, so that it is among the most essential parts of the body. The toes are four, of which the two middle ones only are sufficiently developed for being the common points of support to the body in walking, but the other two are more developed than the corresponding ones of the ruminating animals, and are furnished with small and pointed hoofs. The two principal toes have some lateral motion, and can be brought together or separated, and where they are far separated from each other the two small ones come in contact with the ground, and the plant of the foot is considerably enlarged. This structure of the foot is, as we shall see, very well adapted to the surfaces upon which the animals range when in a state of nature. The females have twelve mammae, some pectoral and some ventral, and the litters of young are numerous. The skin is thick, but soft and pliable, capable of much extension, but not constricting so tightly as that of many other mammalia. The covering consists of stiff bristles, each of which is formed of several small filaments firmly soldered together, except at the points, where they are often separated. Below this there is sometimes a sort of coarse woolly hair; but both parts of the covering vary much with the climate, and in the domesticated ones with the kind, some being very smooth in the coat, and others almost naked. They have a tendency to accumulate under the skin a great quantity of fat, which is popularly called lard, and is something intermediate between the fat of other mammalia and the blubber of the *Cetacea*. In very hot countries this fat does not accumulate in such quantity as in colder climates, and very cold latitudes are not favourable to the animals.

They occur in both continents; but the American ones are so different from those of the eastern continent that they require to be separated as a distinct subgenus. They are of a much smaller size than the eastern ones, but less useful to man, and more limited in their distribution, being met with only in the humid woods of the central parts of South America, to the eastward of the Andes; but in some parts of these woods they are very numerous. In all places of the world they are partial to humid places, fond of wallowing in the mire, and of basking in the sun near the margins of pools and streams.

In the eastern continent they are far more widely distributed than in America; but always more abundant in the damp forests of tropical countries than in higher latitudes. In Europe they occur in a wild state, only in a few of the more wooded parts of the centre and the south; but they once appear to have

been much more general. For many years there have been no wild hogs in any part of Britain, but there are many traditional accounts of their former abundance. In the forests of south-eastern Asia, and the rich parts of Africa, they are more plentiful; and they are distributed to many remote isles in the Pacific. In many places, however, it is much more difficult to distinguish between wood hogs which are natives and *aborigines*, and those that have been introduced by the people, and have been turned loose in the woods and multiplied there, than it is in the case of many other animals. Yet in the case of others there are instances in which we should be very apt to regard introduced animals not only as aboriginal natives, but as the most truly natural and characteristic of the country of any animals that are to be met with there. This is remarkably the case with the ox and the horse on the rude plains of South America. We know well from the history that there was not a vestige of any animal resembling them previous to their introduction from Europe; and yet they now literally swarm, as if that were the place of all the globe most favourable to them. It may be the case with the wild hogs of New Guinea and the Pacific Isles farther to the east; and this appears the more likely from the fact that they are not found except on islands, the shores of which at least are peopled by a race appearing to be of the same climatal variety of mankind as the Malays. Indeed the tame hogs of the east of Asia appear to be from a different variety of wild ones from that of which the remnant is still to be met with in the forests of Europe.

Hogs in a wild state are much more numerous and widely distributed than either oxen or sheep; but it is not on this account the less difficult to trace the parentage of the tame ones, or fix with any thing like certainty the locality of any, or at least all, of those that are found wild. From the fact of the hog being possessed by many races of rude men, who have neither the ox nor the sheep, it is very probable that it was the first animal that man domesticated, and probably the first that he killed in the wild forests. The hog is much more an animal of the tangled woods than any other of those which are, on account of their size, valuable as animals of the chase. From the concealed situations in which they are found, and their habits of basking in the little openings of the woods, they are more easily approached within the range of an arrow, a javelin, or even a club or other manual weapons, than animals which range in the open places, and set a watch when they feed. They are also much slower in their movements, and retreat to shorter distances, making more noise and bustle in their retreat; and thus they are more easily followed. The rate at which they breed also conspires to render them very capable of keeping up their numbers with a large surplus in those woods where fallen fruits at one time of the year, and albuminous roots at another, furnish them with an ample and constant supply of food. It is certain that, in former times, very much of the western parts of the eastern continent was covered with thick, damp, and productive woods, much more so than at the present time. Various kinds of oak, beech, chestnut, and other trees, abounding with farinaceous and oily fruits, all of them rich, and many of them readily eaten by the rude people of former times, rendered, and where the deciduous forests remain still render,

the fall in the forest a most abundant time for the wild hogs. Then in the clumps, by the margins of the pools and the banks of the tangling and intercepted streams, there were many succulent roots; and these roots must have furnished a supply both where the autumnal produce was exhausted, and during the heat of the summer. In all places where the people inhabited the woods, and there were wild hogs in them, these hogs very naturally presented themselves as an abundant and easily acquired article of food.

Canning's keenly satirical account of the origin of cruelty is thus, in all probability, something more than the mere production of poetic fancy. Man, in a state of perfect innocence, and with hands all-unstained by the blood of a single living creature, ranged the wild woods, contending with monkeys and macaws for "fruits in their seasons," and with the wild hogs for fern and other roots, when no fruit was to be found. Whether the rivalry occasioned any jealousy of the hog, and beech mast had any influence in making man more cruel and carnivorous is not said, though it is not impossible, and would add to the truth of the application and the force of the moral. But upon one day of more than ordinary desire, man eyed with complacence the sleek rotundity of a fat hog; and the longer that he gazed, the more ardent waxed his desire of making a mess of the unsuspecting animal. Invention, for Canning did not call in the aid of the devil to bear the burden of the crime, if crime it was, set about to find means of making a meal of the hog. The bow was made and strung, the arrow was pointed; the bow was bent, the arrow set on the string—and,

"He twangs the bow, the hissing arrow flies,
And darkness seals the gentle porker's eyes."

Once tasting the luscious flesh of the hog, man could no longer be contented with the beech mast and the acorns, but soon began to "kill and eat" the whole of living Nature around him. Nor was he content till he had numbered the flesh of his own race among the dainties of his board. As he became more refined, the disposition to eat his fellow men became weaker; but the killing propensity has continued, and the slaughter of mankind, so that it is carried on upon a scale of sufficient grandeur, is above all others the work for which man is especially "covered with glory."

Such, in part at least, is the outline of the fable. In so far as man is concerned, we leave the propriety of the application to the judgment of the reader; but there seems every reason to believe that the hog was the first animal of any size, inhabiting the land, which formed a regular portion of the food of the human race in a state of nature.

The hogs are conveniently divided into two subgenera, those of the eastern continent. The first are the true hogs, or members of the genus *Sus*; and the second are the peccaries, or members of the genus *Dicotyles*. We shall briefly notice both of them in their order.

Sus. The true hogs have six incisive teeth in each of the jaws, the canines in the male long, and projecting out of the mouth, and the cheek-teeth twenty-four or twenty-eight, the anterior compressed, and the posteriors with tuberculated crowns. None of the cheek-teeth have the bone and the enamel alternating with each other, so as to form a grinding surface, as in the ruminantia, and in those pachydermata that are exclusively herbivorous. They have

but one case of bone, with the enamel placed upon it as it is in human teeth. The jaws have no lateral or grinding motion; they merely open and shut, and the food is divided by different strokes of the jaws against each other. In consequence of this, hogs are very clumsy feeders, and scatter their food about. Their mouths are not well adapted for eating any more than they are for grinding; and thus, when their food is in large masses, they hash and mangle at it in a very rude way. If it is tough, they use the fore foot for holding on, while they seize with the teeth, and tear it asunder by an upward jerk of the head. The structure of the head, and the great depth and strength of the neck, fit them well for the performance of this kind of labour, which is, in fact, partly the same as that which they have to perform when they root up the ground in quest of the vegetable stores that are below the surface. The hind toes and their hoofs are well developed, and contribute much to bearing the animals up when they range the soft and marshy grounds in quest of the roots of plants.

It appears somewhat singular that the flesh of the hog was prohibited in the ceremonial of the Jewish law, which, borrowing from the Jews of course, as much of the koran is borrowed, has been adopted by the Mahommedans. It does not appear, however, that this part of the law was at any time very rigidly observed, especially in the later period of the history of the Jews as a nation; for we find swine and swineherds often mentioned in the historical parts of the New Testament as subjects of familiar illustration. This matter, however, being wholly of a ceremonial nature, and without any reason that we can assign, can make no part of the useful history of the animal. We shall, therefore, proceed to a very brief notice of the species. Of these there are three, besides some apparent varieties, and innumerable varieties or differences of breed among the domestic ones. Of one species we have already given a short account in the article *BABYROUSSA*, in this work, to which the reader is referred; and we have also given an account of another, which is sometimes considered as only a species of this subgenus, in the article *PHASCOCHÆVUS*, to which also we refer, and confine the present notice to the remaining ones.

The Wild Hog, or Wild Boar (S. scrofa). This is generally regarded as the parent stock of all the tame breeds in Europe, the north of Africa and Asia, except the extreme east, and that it is the same species with them hardly admits of a doubt, though there are climatal differences of the wild one, just as there are still greater differences in the domesticated, arising from the influence of climate and treatment jointly. But these very circumstances show the flexibility of the animal, and, consequently, that it can be introduced with advantage into almost any climate that mankind can inhabit; and the many and variable kinds of foods upon which it can subsist render it still more pliable in domestication, and therefore more valuable.

The wild hog is all over of a blackish-brown colour, sometimes brindled by the brown being redder in one part and blacker in another; and when these differences occur, they are generally in cross stripes, which are not strongly marked, but pass into each other. There are very long and coarse bristles upon the spine for almost its whole length, which are partially erectile when the animal is excited, and have

a formidable appearance. The eyes are very small, but expressive when the animal is tranquil, and they are fiery and glaring when it is irritated; the ears are not nearly so large as they are in many of the domesticated breeds, but they admit of a very considerable degree of motion. They come to what may be considered as their most active size in about five or six years, but they live to the age of almost thirty, and increase in size and in passive strength and daring hardihood of character during the greater part of that time. They, however, become fertile long before they reach their full size, for they are capable of breeding in their second year. The litters of these immature ones are, however, not numerous. In the wild forests of Europe the rutting time is in January or February, and commences, though more rarely, as early as November. Previous to this time, which is the season of abundance with them, as the fruits of the trees are on the ground, they assemble in small herds; but when the rutting time comes on they separate. Though they are monogamous, the males, or boars, which are exceedingly fierce at that season, often fight desperate battles of gallantry; and it is said that the largest and most powerful males fight to obtain the largest females, which, on their part, are also more favourable to the powerful and victorious than to the feeble and vanquished. In this way, the female which no one courts is left for the male which is not able to obtain another in the strife. There is, however, said to be something like a principle of honour in these battles; for, if a female shows a very strong and determined attachment to one particular male, the rest do not forcibly interfere, but allow him to lead her off quietly to the nuptial bower. Something similar to this appears in many other animals, and there appears to be a sort of natural congruity or propriety in it. We have said that the litters of the ones which have not attained their full size are not so numerous as those of the mature age; this is true, whether both parents, or only one, are immature; and in the case of one, it matters not much whether that one is the male or the female. Thus, in the case of an unequal match, there is a waste of the productive energy; and as this energy is the grand result to which all the developments of animals lead, nature takes every means for regulating it with proper economy.

When all the hostile encounters, and other parts of the pairing are settled, which have no inconsiderable resemblance to the pairings of some birds, the whole separate, each pair betaking themselves to the deep cover of a thicket, where they remain about thirty days. The period of gestation is four months, and the litter consists of from four to ten pigs, according to the age and vigour of the parents. When they are produced, the female hides them very carefully from the male, as, if he were to find them, he would eat them up. Indeed, when the season is severe, and provision is not easily obtained, the female does not scruple to eat her own offspring. This sometimes happens in the case of the domestic sow; and Shakspeare mentions, among the fitting subjects that go to the composition of a diabolic mess,

"Sow that hath her farrow eaten,"

which he of course borrowed from the then popular notions of what subjects were fit for the purposes of witchcraft. That there should be hostility to the young on the part of the boar is rather in accordance

with a somewhat common habit among animals; for in those species, whether mammalia or birds, in which the males fight battles of gallantry, they never take any share in providing for the young, always treat them harshly, and not unfrequently kill, if they do not eat them. There is even a shade of the analogy traceable among the human race; and we might, upon very sound physiological principles, assume that such might be the case; for it is to be understood that battles of gallantry among men, whatever name they may get, and whatever aspect they may put on, are in reality animal matters, not intellectual ones; and in the case of mothers, too, it very frequently happens that those who display the warmest animal affections for their children are the most prone to destroy them, both in an intellectual and an economical point of view. There is thus a lesson of practical instruction to ourselves to be drawn from the study of almost any animal to which we can refer; and this we might expect, as the animal is so much mixed up in all that we derive or do with reference to the present world.

If the young are protected, and the mother finds the necessary supply of food in the early stage (for it is in the very early stage that there is danger from her), she becomes a most attentive mother. The period of suckling is of the same length with that of gestation; but the protection of the mother is continued for a long time after this; and no parent can be more bold in the defence of an offspring, and no offspring more attached to a parent.

There is something more curious even than this in the economy of the wild hogs, something very closely resembling the founding of a sort of clan; so that those persons who are fond of tracing what they call sagacity or intelligence in animals may find it here. The litter are not only attached to the mother, but to each other; and this attachment does not cease when they are no longer dependent on the mother's protection, but after another litter has been produced; nay, it is communicated from litter to litter, till the produce of the same mother form a little colony, the members of which appear capable of recognising each other, even after they have been separated for a time from physiological causes. It is possible that most herds of social animals are originally formed on this principle, though the attachment has not been so well observed in most of the others as in these.

But this has a limit, and it is easy to see that it should; because, with the great fertility of the animals, and the small disposition that they have to range far from the same place, they would in no very great length of time become so numerous as that no pasture could maintain them, and thus the free and average operation of the principle of reproduction would in time effect the destruction of the race, the more especially when it is considered that the natural period of life in them is thirty years. But nature is never without a resource, exactly adequate to the necessity that there is for it; and though while we, in the exercise of our limited powers, in general see only one part of the case, and so see it as though it would in the end lead to destruction, yet there is always another power which comes in at its appointed time, and works for preservation. This holds in every case, although many of the greater changes appear to be connected with wide extending ruin.

In the case of the wild hogs, the correcting principle that limits the numbers of the individual herd,

and enables herd to succeed herd, just as generation succeeds generation, is both simple and easily seen. The young do not come to their full growth till the age of five or six, but they begin to breed at two. Till they attain their full growth, the attachment to the parent herd continues; but after this it ceases, and each pair, as they arrive at this stage, go off to found a new colony in a part of the forest which does not interfere with the pasture of that from which they take their departure in order to make room for other races. When the young of the year are so far advanced as that they do not greatly need the protection of the mother, the whole of the herd assemble and feed socially together, until the season again comes round, at which they disperse in pairs. When they are in the herd they are always under the leadership of a male that may be looked upon as the patriarch; though he does not exercise the same kind of sway as the patriarch of a polygamous race. After they have assembled in the herds they are apt to sally forth from the forests, and do no small damage to the cultivated fields, both by rooting up and by trampling down. There is an allusion to this in the beautiful parable of the vine in the eighteenth Psalm: "The boar out of the wood doth waste it, and the wild beast of the field doth devour it." This is finely true to nature, even in the contrast of the mischief done by the two. The wild beast of the field devours—simply eats, but the boar out of the wood wastes—tramples down and destroys.

The leader of the herd is usually at some distance from the rest, but they do not spread far; and as their vision is neither keen nor extends far, they are understood to proceed chiefly by scent; and this is the further necessary that the night is the time at which they commit their depredations. When the herd are attacked, they form in a circle with the weaker ones in the centre, and make a most formidable resistance, standing boldly out to meet the danger. If wounded by a shot, even when surrounded by the dogs, the boar will instantly turn in vengeance upon the hunter.

The hunting of the boar is a favourite field sport, but it is one which is not unattended with danger. The male when living apart affords the most dashing sport. Common sporting dogs will not do; for strength and weight, not swiftness or address, are required; and thus large mastiffs, or crosses between large mastiffs and bull dogs, are employed. When drawn from its course it does not run off, as it would find but little safety in flight. It stalks off with glaring eyes; and if the dogs run in upon it before it is a little winded, it finishes them one by one with a single application of the tusks. Old boars are not quite so formidable as those which have about gained that age at which they separate from the parent flock; and these too happen to be the ones that are most readily found. They can hold out longer, so that the dogs are more fatigued; and the tusks are sharper and straighter, and inflict more deadly wounds. The hunting of the wild boar is, however, a subject which does not directly belong to natural history. Hog-hunting in the woods is a favourite sport in India; but we believe that the wild hog there is not quite so formidable as in more temperate climates. This would lead us to suppose that the proper locality of the animal is not in the very hottest parts of the south; for, even in the islands of the South Sea, which are in point of fertility, and of course of abundance of food, superior to most

other regions, the native hog is a smaller animal than the wild boar of the European forests; and it is different in shape and colour—its legs are very short, and it is black; still it does not appear to be any thing more than a climatal variety. There is one other particular connected with the varieties of hogs to which it is worth while to attend. It is this: they seem to be much more easily broken into varieties by mere change of place than most animals; but when once a variety is established in a district, it appears to be more constant.

The domestic hog is an animal of very great importance in an economical point of view; but it is one of which, on account of the almost endless variety of breeds, it is impossible to give a detailed account in a sketch. In a merely natural history point of view this is not necessary, because, in all its characters, generic and specific, it is identical with the wild one. All the varieties that have been tried breed freely with each other, and the progeny is fertile in every race. This is quite enough to prove that the species is only one; and not to show this only, but further to show that varieties without limit may be obtained by crossing and by changing from place to place. Though the same breeds vary greatly in size, none of them is so large, or nearly so powerful an animal as the wild boar; and thus if, in breeding with a view to any of the points that are held as being most valuable, the size and strength should be reduced below what may be considered as the proper standard, crossing with the wild boar will bring them back, though it is said that crosses near the pure blood produce much more vicious animals than the breeds that are removed from it.

In a highly improved state of a country, the hog is certainly not entitled to take precedence either of the ox or the sheep in point of utility, its uses not being so many or so general; but still it is a very useful animal; and there are some states of a country, or at least of particular districts, in which it is more valuable than either of the others. The milk of the hog is not, we believe, used as an article of food in any place, though there is not the least doubt of its being wholesome. It can, however, be much more advantageously applied to the purpose for which nature intended it, as the young are of some value (though not wholesome as a food certainly) at a very early age; and they grow much faster than any domestic animals of nearly equal size.

Upon an arable farm, where hogs are only a subordinate article with the farmer, the estimate is that with two females and one male, managing them so that they may be always in the highest state of fertility, the succession may be kept up, and forty fed ones sold every year, besides some of the young, at an expense of about twenty pounds, besides the waste about the farm which could not be profitably applied to the keep of any other animal. The trouble which they require is not great, and thus, at the very lowest estimate of them, there would be a profit of between 300 and 400 per cent. upon the absolute cost, which is far more than can be obtained from any other animal that can be kept on a farm. No doubt the breed must be skilfully chosen, and the treatment must be judicious; but these are essential to success in every thing that is cultivated. The average estimate is that twice the same weight of food may be obtained from hogs, taking the bad breeds with the good, that can be obtained from the same cost of food by means

of any other animals; this too on the supposition that the flesh of the hogs is all of good quality. The tendency that hogs have to fatten in the autumn and early winter even of the first year, and the superiority of young pork, are greatly in favour of this. During the time that intervenes between the calf and the bullock, and the lamb and the sheep, neither of these animals can be "forced" into fat, except at great expense; and as this is working in opposition to the natural tendency of the animals, the flesh when fattened is of inferior quality. Not so with the hog; for with it the art merely seconds nature, and consequently the quality is good.

There is another advantage: oxen and sheep must have range and free air in the period of their growth, as they are both ranging animals in a state of nature, otherwise they are diseased and absolutely unwholesome. Neither can you obtain the flesh of hogs of the very highest flavour and quality, unless they too are sometimes in the open air, but even then they require a very limited range; and good and wholesome pork may be grown and fed in a state of perfect confinement. While the hog is growing, the food, if clean and in sufficient quantity, is not very material; because in the natural state of the animals their summer food is not of the most nutritious kind. The fruits of the preceding year are all gone, and the roots which were albuminous in the winter are exhausted by the operation of sending up the stem, the leaves, and the flowers of the year; so that during that season the hogs are in a great measure reduced to the condition of herbivorous animals; and if they are in a state of confinement, clover or green tares, or any other of the succulent plants grown for stock, will keep them on till the season of plenty comes; that is, till they come in for their share of the plenty of the harvest, a share which, when they are not there to get it, is almost entirely lost.

To the cottager who has a garden, as every cottager ought to have, not merely for its direct advantage as supplying many necessities which could not otherwise be had, but because it attaches the man to his home, and prevents him from spending his leisure hours in an improper manner—to the cottager the hog is a very valuable animal, and will always pay the rent of the cottage, if properly managed, and of the right breed. The breed is a very important matter, because the same food that will fatten one for the market will barely suffice to keep another alive.

There are many worse ways of distinguishing one country from another than by their pigs; and the same applies even to different districts of the same country. In Britain there are three of what may be called leading or typical breeds; but they are so much blended by crossings, or changed by differences of situation and treatment, that it is not easy to draw the distinction between them in every case. Two resemble, in many particulars, the wild boar of Europe, and may have been procured from that animal when it was indigenous in the island. Of these two breeds the one appears to be the result of breeding in the rude parts of the country, where there were abundance of acorns and other wild fruits, and good shelter and keep at all seasons. These are generally called the Berkshire breed; but they are distributed over many parts of the country, and broken into a great number of varieties. These are generally of a reddish colour, with black spots, and large ears hanging over their eyes. They are

short-legged small-boned animals, and much disposed to fatten; but they are not well adapted for bleak situations, or for ranging over rough grounds.

The other breed, which we may consider as more immediately referable to the wild boar, has characters rather the reverse of these, or rather different from them. The body is long, and so also are the legs, and the bones are large. This is the breed of the less fertile districts, and it is usually styled the Highland or Irish breed; but it does not appear to have been more originally confined to these parts of the empire, or to either of them, although it is unquestionably the best adapted for cold and rough places, or where much systematic attention cannot be paid.

The third of the leading breeds, which may be considered as originally distinct, that is, that no one of these has been bred out of the other, by attention to circumstances on the part of the breeder, is what is usually called the Chinese breed. It is generally of a black colour; but that is not the essential distinction; for, though colour is perhaps more constant in hogs than in some other cultivated animals, it is not absolutely constant. The permanent characters of the Chinese breed are the short legs and body and the great roundness and depth of the latter, in consequence of which the belly nearly touches the ground when the animal walks. It is of little consequence whether this breed was or was not imported into this country from China; for we do not happen to know so much about the forests of that country as to be able to say that this, or indeed any other species of hog in the wild state, is to be found in them or not. We know that all its leading characters are different from those of the wild hog of Europe, and that they resemble those of the hogs that were found wild in the islands of the Pacific when those islands were first visited by Europeans, and when there was not even any traditional history of their existence among any of the nations of continental Asia. That, under these circumstances, China, or any other part of the continent, should have received a stock of hogs from those islands, is very unlikely—we may say impossible; and this appears more strongly when we bear in mind that those isles of the Pacific, instead of being fragments of a former continent, of which the greater part has been submerged, are apparently newer formations than the continent of Asia. They are, for the most part, either volcanic, or composed of coral rock, both of which require the sea for their foundation. In the meantime, however, we have to do with the hogs only, and not with the question of their descent from a wild stock in any part of the world. They agree best in character with the Oriental ones, of which we have been speaking; and therefore, the best way of getting rid of the difficulty, which we cannot solve, is to refer them to that origin. Nor is this referring wholly without its use, for it points out the situation in which the animals can be reared to the greatest advantage. They are found native in places which have what may be called a perpetual summer, and where wild fruits and farinaceous roots can always be obtained in the delightful shade of the woods, with very little motion from place to place, or other exertion on the part of the animals. They are evidently formed for such places by the comparatively small development of their organs of motion; and thus, in what may be called the pure state, they are quite unfit for rough and bare places;

and in situations where they had to roam about and merely consume the scraps, they would be most unprofitable. As compared with what we may, from present observation on the continent, consider as the type of a wild hog in Britain, this Chinese breed is in the most artificial state; and thus it must be best adapted for those places where the climate is mild and the soil rich, and where the breeding of hogs has been reduced to a regular system.

The three leading breeds of hogs which we have mentioned afford a more distinct means of assigning these animals their proper "locations," according to the nature of the places, than we have in the case of any other animals; and the almost endless variety of circumstances under which hogs may be kept to advantage, renders this a very important matter to all classes of our rural population. Oxen and sheep cannot be profitably fattened except on a large scale; but any who has room to hold it may profitably fatten a hog. We do not of course recommend that, *more Hibernicæ*, it should be kept in the house, at bed and board with the human inmates. This is not a seemly way of doing the business, and yet it is one of the strongest possible proofs of the great value of the hog. An Irish labourer and his family, who "rint a quarsther" of a cellar or a garret in some squalid den in the British metropolis, often have a pig in the fraction of an apartment, which eats of the same potatoes, reposes on the same straw, and is in fact to all intents and purposes a member of the family, not merely tolerated, but loved and loving; for though hogs are sullen and stubborn animals when one attempts to lead them captive, and require to be pulled backward in order that they may be impelled forward, yet they are susceptible to kindly treatment; and a hog may not only be taught to follow its master, but there have been instances of training them to point at game like dogs, and there is not a country fair in England where the powers of "Toby the wise pig," in the mysteries of divination, are not the marvel of the rustics.

It is not, however, for the purpose of playing the pointer, or astonishing the natives with the wisdom of Tobias, that the pig is kept with so much care in the cantonment of the cellar or the garret. It tells a tale of the great and paramount value of the pig to the poor man, and a tale of Ireland—a tale of most monstrous and most heart-rending injustice on the part of somebody, but with the latter we have no concern. The tale of the pig is, that without it the poor man in Ireland could not keep the tenancy of the mud cottage reared by his own hands on the margin of the health-invading bog, that the pig finds the annual impost which the man must pay for being in that state of "glorious independence," in which no wind can blow upon him with a more bitter blast, and no contingency of events can depose him of a single comfort.

Now, if the hog is thus, as the case of millions has proved, a sheet-anchor by which man can ride out the topmost bent of misery's tempest, how well may it serve those who can have it all to themselves? This of itself gives a popular interest to the animal, far above that which is possessed by the veriest marvel in mere natural history. Nay, there is more depth of pathos, and force of moral and social instruction, in a single hog, circumstanced as we have mentioned, than in all the formal zoological collections on the face of the earth. But the reader can pursue it for

himself, while we proceed with the routine of our article.

We shall just run over the outlines of a few of the leading breeds, which have been formed out of one or more of the three principal ones. The Berkshire, which also chiefly prevails in north Wilts, and some other places, is remarkable for the compactness of its form, and the quality and quantity of its flesh. Small boned as it is, there have been individuals twelve or thirteen hundred weight. The Hampshire hog is longer in the body than the Berks, and not so compact and handsome, and it is more inclined to white in the colour—an approach, but a very slight one, to the mountain breed. It is, however, easily fattened, and valuable. The Sussex hogs resemble the other southern breeds, that appear to be related to the Berkshire. They are black and white in large patches, the white being often in one mass placed about the middle of the length. On the borders of Wales there are some large and coarse breeds, of clumsy form and not very profitable. The Cheshire are white in the ground colour, but with large patches of black or blue. They have great heads, large ears, long and stout legs, and their skin hangs loosely about them, so that, though they are moderately fat, they are never plump in appearance. The Shropshire is an analogous breed, although not quite the same as the Cheshire. They are white or sand coloured in the ground, with patches of black, less abundant and smaller than those upon the Cheshire. They are rough and shaggy-looking animals, with numerous long and strong bristles, and a good deal of rough hair among the roots. They have large bones, and are not very profitable for ordinary treatment; but when fattened on grains, at breweries or distilleries, they yield a great weight of fat but coarse pork. The two breeds last mentioned are still nearer to the mountain breed than the long-legged hogs of the south. The Suffolk breed, though different in colour, being in general without patches, is like those of the border of Wales, high on the legs and long and thin in the body.

In what we may consider as the mountain hogs, or those that have had their characters for a long time moulded to the more inclement atmospheres of our islands, there appear to be two varieties, one of the mainland of Scotland, and one of the islands; and as both of these are very variable in their localities, there are numerous shades of difference among the hogs. The native breed of the west Highlands and western isles are of small size, and of a sort of silver-grey colour. Their coats are shaggy, being abundantly supplied both with bristles, and with coarse under wool. These animals are remarkably hardy, and, for the greater part of the year, they find their own food on the hill without any cost of artificial provision, and very little trouble of any kind. They do not get fat in this situation, as compared with the southern breeds, but their flesh is of very good flavour; and when they are brought down to the low country, they are rendered very fat and excellent in a short time, and at comparatively little expense.

In many parts of Scotland the people have a strong prejudice against hogs. It cannot be called a religious prejudice; but, like other superstitious prejudices, it borrows the phraseology of religion; and it is, or at least used to be, not uncommon, in many of those places where hogs could be reared with the greatest advantage, to hear the folks object to their

A A A

Introduction with a solemn shake of the head: "They were forbidden under the Law, and the Devil ran away with them under the Gospel; so how could they be wholesome or proper food for any *Christian*?" Yet in the western isles, and all the rainy parts of the west Highlands, it is doubtful whether the people could turn their attention to any thing so profitable as the cultivation of their own native hogs. The climate is ill adapted for corn crops, and the greater part of the surface is too steep for the plough, though, as the climate on the low grounds is mild as well as moist, ordinary management might raise potatoes and turnips in almost any quantity. Sheep are ill suited for the dripping sky, and, though the flesh is good, a whole quarter of mutton would be but a scanty meal for one hungry man. Black cattle are reared in abundance in the larger islands, for the rain does not injure them as it injures sheep. But they can be profitably raised only on the large scale, as there must be a breadth of hill pasture for the summer, and a corresponding extent of shore land, or holm, for wintering. The cattle are thus confined to the large graziers; and as there is no scope for fattening cattle, and no market for their flesh although there were, they are sent out of the country young, in order to be fattened and consumed in other places. None of these disadvantages are connected with the hog. The native one is well defended; and besides wet, which would destroy sheep, is health to hogs.

Common Hog.

This subject is eminently worthy of attention, and it seems passing strange that none of those "most learned and humane patriots," who charge themselves with the important task of schooling the simple people of remote districts in the art of making their situation more comfortable—and generally deserve to be well birched for raising false hopes, and making the cure worse than the disease, have never schooled the people of the remote Highlands and isles in the art of extracting the vast volume of comfortable enjoyment—to say nothing of safety from starvation, which is embodied in the carcass and capacity of their own little grey pig. Even while we write, there are meetings and speeches, and ample subscriptions for the relief of the destitute people of these remote and highly interesting isles of the sea. That, as a temporary matter, this is well, no one will of course doubt for a moment; nay, it would be criminal, abominable, if they who are encumbered to surfeit and disease with the fat of the land in one part of the kingdom, allowed their fellow creatures, haply their betters in the judgment of reason and in the sight of Heaven, to perish of famine in another part. But it is at best a paltry palliative. There is no vital principle, no permanent healing in it; and if the seasons again come round in the same manner, the grief of the famine which will then ensue, will not be in one

jot taken off by the present almsgiving, however ample. If, however, the people were schooled into the way of turning the resources of Nature in their own locality to the proper account, the charity of the instruction would be as the fertilising dew of Heaven, and the relief would be from the cause of the evil, not merely from its temporary pressure, as it is in the present case.

Well, much might be done by means of these same little grey hogs, which have wiled us away into this digression. Now that the salt duty is repealed, which erewhile fell like a pestilence upon the produce of land and sea in these remote places, and did not, from them at least, bring in as much revenue in ten years as would have paid for a royal shoe latchet—indeed, the longer the period the less the result, as the tax raised never half paid the local officer—now that this is at an end, there is really no reason why every poor man in those remote places should not annually salt down the flesh of two or three grey pigs as a store against the evil day, or a little luxury if matters went well as to the season. We are not aware that the quantity of any thing else having the least value to any body, would be in the least diminished by the keep of the animals; and if the islander but once tasted a bit of properly pickled pork along with his daily and nightly potatoes, we feel quite convinced that he would very speedily feel himself absolved from the Mosaic injunction, and relieved of all apprehensions of swallowing a "legion of devils" in a gammon of bacon.

In the northern isles the native hogs are different in the colour from those of the west. They are reddish-brown or blackish, or brindled of the two colours, and their bristles and also their under wool are longer and still more abundant. The probability is that they are nearer by several crosses to the wild boar, as the probability is that they came at first from Scandinavia, and not from the mainland of Scotland. They are not so important there as in the west, because the inhabitants are more skilful and industrious in their fishing.

The mainland breed of Scotland are expelled from all the more highly-cultivated parts of the country, and better breeds substituted in their stead. The natives are neither handsome nor profitable. They are shaggy, skranky animals, with long legs, high rough manes along the whole line of their backs, and very thin bodies. They are expensive to feed into any thing like tolerable condition, and they are not very good even when fattened. Their fat is curdy, and the muscle is coarse in the fibre; and there is no very pleasant flavour. In every way that their flesh can be cured it is inferior, and when fresh it is still worse. The inferiority of this native breed, and the time and expense necessary for bringing them into any thing like tolerable condition, in all probability, helped much to cause the culture of hogs to be neglected in that part of the country.

The Chinese hogs are generally handsome, small in size, but very compact, and their flesh is easily fattened, and of excellent quality. They are variously coloured—black, white, or the two blended together, but without any brown in the pure race. In the pure state they are tender; but they do well in many parts of the south of England, looking very pretty on the fine green meadows, with their short legs, round and plump bodies, and clear glossy skins almost without bristles or hair. They are "ringed," and thus do not root up and disfigure the meadows of which they have

the run, and upon which they are really ornamental. After harvest they have the run of the fields and of the oak and beech woods, and then the artificial feeding of them is an easy matter. They are small compared to the Berkshire, and they are not so good travellers to market; but their flesh, either recent or properly cured, is a *bonne bouche*—especially with the sauce of an autumnal day's exercise in those parts of England where they are most plentiful.

The cross of the Chinese and the Berks is perhaps the very best hog for keeping as a sort of supernumerary animal on a grain farm; because there are really no bad points in either of the parent breeds. We are not aware that the cross with the grey hogs of the isles has been fully tried; but we feel convinced that it would, though not exactly suited for the hill, be of great value on the low grounds, and about farm-yards and mills, where they occur. Much more might be written on the breeds of domestic hogs in our own country, and the advantages of their general introduction, but we must come to an end. In conclusion we may remark, that in speaking of the fertility of these animals we have taken an average. But there are many cases in which it greatly exceeds this. Two litters in the year, or even five in the two years, may be obtained, though the profit arising from the extreme is doubtful; and four months and a half between litter and litter, is as short a time as is consistent with sound economy.

The masked Hog (S. larvatus). This is a wild species of the interior of Southern Africa, said to be of very ferocious disposition, and certainly not very prepossessing in its appearance. Its general characters are the same as those of the wild boar; but there are considerable differences both in the bones of the head and in the external appearance. The differences in the bones are, a considerable extension outwards of the zygomatic arches of the cheek-bones, and a still greater enlargement of the sockets of the canines in the upper jaw. These last form prominent ridges, reaching to near the eyes, and diverging from each other as they ascend, and each terminating in a considerable knob. These projections of the bone are covered with a thick puckered skin, which gives the animal the appearance of looking from behind a mask which covers the middle of the face from the snout up nearly to the eyes. There is also a little difference in the snout itself. The muscles which move the peculiar bone and the cartilaginous part, have their origin over a greater length of the surface of the nasal bone; and this, with the projections of bone on the face, and the wrinkled and pad-like covering of them, would lead us to conclude that when rooting up the ground it has a much more severe task to perform than the common wild boar. We have no positive evidence of the fact; but the physical condition of the country is in favour of it. This hog has to deal with the earth in a more hardened state. This of course will require greater support to the snout; and the enlargements of the bones, both vertically and crosswise, are well calculated for affording this. The wrinkled covering of the projecting parts, which is not unlike Indian rubber in appearance, may be a good defence against the prickly bushes that are so common in the pastures of this animal.

So far as is known, the masked hog is about the same size as the common one, and, with the exceptions that have been mentioned, it does not differ in almost any particular; whether it has the same habits,

and the same curious system of clanship which we have mentioned in the other, are points which have not yet been ascertained; indeed the woods which this hog is said to inhabit are not the most pleasant places to explore, and the hog itself is not exactly the animal to whose domestic circle one would be very fond of paying a friendly visit.

We shall now very shortly notice the remaining subgenus.

THE PECCARY (Dicotylus). These are the American animals, corresponding to the hogs of the eastern continent, but far superior to them in size, and much more limited in their geographical distribution. Altogether the American continent is very deficient in native pachydermatous animals, as it also was originally in ruminating ones. In the northern part of the continent there was not one in the living state at the time of the discovery by Europeans; and hitherto we are aware of only one fossil species, the *Mastodon*. In South America there are only two known genera, the one under consideration and the *Tapir*, and no fossil remain of any has been found, as the *Megatherium*, the great giant of the grave, is classed with the sloths. This proves that the early state of America must have been different from that of the other continent, but in what the difference consisted we are unable to say, though the analogy would lead us to suppose that there must have been a greater abundance of permanent marsh and rank aquatic vegetation.

The peccaries are abundant in the tropical forests, and supply the Indians with a considerable portion of their food, the animals being shot by means of pegs, poisoned with the wourali, and blown from the tube or discharged from the bow, according to circumstances. They are by no means such formidable animals as the wild hogs, not only on account of their inferior size and strength, but because they want the formidable tusks of the others.

Though classed in the same genus with the hogs by Linnæus, they have been very properly separated, as their whole air is different. A wild hog, even when not in a state of excitement, has a fierce and forbidding aspect, whereas there is something timid and almost helpless in the expression of the peccaries; their details of character are also sufficiently distinct for being reckoned generic. The most apparent ones are the absence of the outer toe on the hind feet, so that there are only three hoofs there, two to the front and one to the rear; and the presence of a glandular pouch or opening on the ridge of the back, upon the first or second vertebrae of the loins, and which has a very considerable resemblance in form, though so different in situation, to the suborbital sinuses of the deer. There are some variations in the number of hoofs on the hogs themselves, some having only three on the foot instead of the normal number four. But when this happens it is never either of the hind toes of the foot, which are the external and internal ones in the arrangement that is wanting, as is normally the case on the hind feet of the tapirs, it is the two middle toes that are united, and enclosed in a single hoof. Another obvious character of the peccaries is the size and form of the tail. The tail of the hogs is not large, and we can hardly believe that it is of much use to them in their march, but it is always cylindrical, and in many of them it curls. The tail of the peccaries, again, is not above an inch in length, and flat and broad; the peccary also stands rather higher on the fore legs

than on the hind ones; the neck has an inclination upwards, and the head is carried higher than in the hogs. The outline of the back is also different; in the hog it is almost a uniform convex curve from the nape to the rump, at least in the more plump breeds, where they are fattened; but in the peccaries, it is a curve of a contrary flexure, being concave behind the shoulders, and convex toward the rump. The body of the peccary is thick and paunchy, as are the bodies of all the pachydermata, but still the outline of the back indicates more elasticity and freedom of motion in the spine than the hogs possess; it is the want of flexibility in that part which makes the hogs dodge in so remarkable a manner up and down, when they gallop, and which makes this motion so fatiguing to them in proportion to their actual strength. They not only carry forward the centre of gravity of the body, as is done by every animal, however smoothly it may walk or gallop, but they lift it up and let it down, and also shift it backwards and forwards, in the course of every step that they take. Moving the centre of gravity of an animal is the very same as moving the whole volume and weight of the animal; and in as far as the motions are up and down they are very fatiguing. Say that a fat hog of half a ton tries to gallop, and it has to lift half a ton from the ground at every leap, while it comes down with the momentum of the weight of the same, as acquired from the depth of the descent. This, by the way, is the reason why pigs, when they run over a garden, do so much mischief with their feet as compared with smooth running animals of equal weight; it is also because the porpoises make similar boundings in the water, in consequence of the stiffness of their spine, that they get the name of sea hogs.

The peccaries are not wholly exempt from this bumping motion, but they have it in a much less degree than the hogs; and thus, if they are less powerful in repelling an attack, they are better able to escape from it by flight. The teeth of the peccaries are, four incisors in the upper jaw and six in the lower, one canine in each side of each jaw, but not projecting out of the mouth as in the hogs, and six cheek teeth in each side of each jaw; the cranium of the peccaries is very short, and in this respect it resembles that of the baboussa much more than any other of the genus *Sus*, and the lower jaw is so locked in its articulation, that it has even less lateral motion than theirs, limited as that is.

Both the species of this genus are gentle and harmless animals, living in the rich forests, and not requiring or possessing any degree of resource. They keep together in packs, which appear to have considerable attachment to each other; but, though it has been said that they combine for mutual defence against the jaguar, and even against man, and that their united efforts are sufficient to destroy either the one or the other, yet it does not appear that there is any truth in these sayings. The desire of personal safety appears to get the better of every other upon these occasions, and the pack may be destroyed one by one without any of the survivors appearing to take the slightest interest in the fate of the fallen. The Indians seem to be well aware of these circumstances, for when they meet with a herd or pack of peccaries they are sure to return to their places of abode loaded with provisions. There are two species of this genus, or subgenus, of which we shall give slight notices.

The collared Peccary (D. collaris). This species is about two feet and a half in length from the point of the muzzle to the base of the tail, and it stands a foot and a half high at the shoulder, and a foot and eight inches at the most elevated part of the crupper. The hair with which it is covered is thick and rough, annulated with alternate black and white, which gives it the appearance of being dotted with these two colours. On the neck the white predominates, and this gives it the appearance of having a collar, from which circumstance it has obtained the common name given to it. The legs and feet are entirely black, but the whole skin of the body is of a livid whitish colour; the pupils of the eyes are round, but it should seem that their sight is but feeble, and that, as is the case with the hogs, smelling is the most powerful of their senses, and the one upon which they have the principal dependence in the finding of their food, which they do in the twilight, basking and reposing in the little glades of the woods during the heat of the day. In this species the tail is little more than a mere rudiment, and the female has only two mammae, which circumstance alone would be sufficient to distinguish them from all the hogs of the eastern continent. The glandular pouch on the back gives out a strong smell of garlic; but the use of the pouch or the secretion in the economy of the animal, is wholly unknown. This odour is given out in the greatest abundance when the animal is irritated, as then it erects the bristles on the neck and along the line of the back, by which means the gland is more compressed than when the animal is in a tranquil state. When alarmed, it utters a sharp and piercing kind of squeak, but not quite so piteous as that which is uttered by a hog in distress; like hogs, too, they express their satisfaction by a softened species of grunting. They are inhabitants of the woods in the lower grounds on the east side of South America; but we are not aware that they have been met with to the westward of the Andes, and they never occur in lofty situations. Buffon committed a curious blunder respecting this species of peccary. The Spanish colonists in Paraguay, from whom he drew the materials of his account of the locality and habits of the animal, use the word *monte* as descriptive of a forest; and Buffon, confounding this with the French *mont*, described this peccary as a mountain animal, which is the very reverse of its proper habitat. The same eloquent, but fanciful and not very accurate describer, represented the pale-coloured collar, which obliquely surrounds the neck of this species, as a dorsal stripe extending along the ridge of the back.

These animals are found in pairs in the breeding season, and at these times they rarely, if ever, come out of the forest. The female produces, as is understood, only once in the year; and the young are generally two, and never more. They are easily tamed, and fond of being caressed, but they are also impatient of restraint, and if detained against their will, they not only erect their dorsal bristles, and utter their war cry, but attempt to bite, which they do pretty severely. Some that have been kept in menageries in Europe, have shown much docility, as compared with the hog when in the wild state. They preferred fruits and farinaceous vegetable substances to any other kind of food; but still when that was not given them, they could be very miscellaneous in their feeding. Well-known as these animals ought to be, there have been some mistakes about them; and the man-

ners and numbers of this, which is really the most rare of the two, have sometimes been given to the other, which is a larger and bolder animal, and met with in herds, whereas the collared one seems to be more retiring and seldom met with except in pairs.

The *White-lipped Peccary* (*D. Labiatus*) is a larger animal than the collared one, and appears to be more numerous. The hairs or bristles upon it are much larger, and as the annuli of white occupy a very small portion of the hair, as compared with that occupied by the black, the general colour approaches to black, except on the rump, where it is brownish. The bristles are very long throughout the whole line of the back, and have their upright position whether the animal is in a state of excitement or not; those on the neck, from the occiput to the shoulders, form a sort of permanent crest. The under jaw is entirely white, and there is a considerable quantity of white on the margin of the upper one. The white on the jaws continues beyond the angle of the gape and turns upward in the direction of the ear. The young of the year are reddish in the hair or bristles of the upper part; but they lose this and acquire the colour already mentioned when they come to maturity. This is apparently (for there is not a little confusion in the accounts of them) the species which is said to be formidable, not only to the smaller species of cats which are found in the forests of tropical America, but to the jaguar and even to man himself; but there does not appear to be much truth in these statements; and the jaguar is said to follow the herds of these animals something in the same way that the lion follows the antelope and the quaggas in Southern Africa, pouncing upon one after another according as he is prompted by his appetite. There is, however, so much confusion in the accounts that are given of these two species, that one scarcely knows where the truth is to be found.

The odour given out by the dorsal gland of this one, appears from the accounts to have more of a musky smell and less of the odour of garlic than that given out by the collared species; but this cannot be implicitly depended upon, as in this, as well as in almost every other respect, the two appear to have been very much confounded with each other. It is also probable that the statement that the collared peccaries are found in packs, and the white-lipped ones in pairs only, may have arisen from the observation of them at different seasons. The whole of the hog family are found in pairs in the early part of the breeding time, and all the others are found in packs, when the young are able to shift for themselves; and it is by no means likely that animals resembling each other so closely in other respects as the two species of peccary do, should differ so widely in this particular habit. There is, at least, no parallel case in any other genus, or even family of vertebrated animals. Roebucks, it is true, keep in pairs all the year round; while other deer live in herds, with the males, generally speaking, apart from the females. But then, the deer which have this habit, do not pair at any season; but are polygamous.

The males and females differ but little in their external appearance; but the young which are littered early in the season, are greyish red on the upper part, and have usually more white on the under jaw than the adults. They do not acquire the full colours of the adult state till they are a year old; and as till then they are different from both the species when mature, they have sometimes been described as a third.

Such is a brief outline of the principal members of this interesting family of animals—a family of which the species belonging to the eastern continent are peculiarly useful to man, can be kept in situations where no other useful animal can be kept, and which fill up a place in the economy of the farm, which, but for them, would be an unprofitable blank.

SUTHERLANDIA (Hort. Kewensis). A fine ornamental shrub from the Cape of Good Hope. The flowers are diadelphous, and followed by pods, of course the plant belongs to *Leguminosæ*. It ripens seeds in abundance.

SWAINSONIA (Salisbury). A genus of showy plants, nearly related to *Sutherlandia*, natives of New South Wales, and belonging to *Leguminosæ*. They thrive if potted in any light soil, and are easily propagated.

SWAN (*Cygnus*). A genus of web-footed swimming birds, which are found on the rivers and small pools of fresh water, rather than the sea or the larger lakes, and which, when they do appear on these, are always near the shores, and never on the expanse of the broad waters. The chief reason of this is that they are vegetable feeders, and although their long necks enable them to reach the bottom at considerable depths, they never dive, and they rarely feed upon the land, or in any other mode than by floating on the surface of the water. They are among the most ornamental of all the water birds, on account of their great size, the gracefulness of their forms and motions, and the snowy whiteness of the plumage of those species with which we are most familiar. Swans have, from the remotest antiquity, attracted the attention of poets and other describers, and the ancient fable of their acquiring a musical song when they are dying, instead of the husky voice which they have when alive, is still repeated though wholly destitute of foundation. That it should be true would, indeed, be contrary to the whole analogy of nature, the voices of pain, and especially at the hour of death in animals, being, without a single exception, unpleasant to the ear. Even those song birds whose notes are the most mellifluously sweet when they are in good health, are all painful to hear when they meet with a violent death, the only time at which they utter displeasing sounds is when that catastrophe is approaching them.

In some of the species, the swans approach the geese in many of their characters, while the typical ones differ considerably. The leading characters of the swans, considered as a genus, or as a subgenus of *Anas* are these: the bill as wide at the tip as at the basal part, and the height at the base; the nostrils are pierced about the middle of the length of the bill, and the neck is very long as compared with that of any of the other web-footed birds. Swans feed upon seeds, roots, and various parts of plants which are blanched and succulent by being under the water. They therefore have the gizzard strong and muscular, and the intestines and cæcal appendages very long. It is sometimes said that they eat various kinds of aquatic animals, but the fact of their doing so is not clearly established. They are to a considerable extent social animals; and where there is sufficient scope and they are not disturbed, they are found in troops, more or less numerous, according to circumstances. In the breeding time they are strictly monogamous; and the pairs take up their nesting-grounds at some distance from each other. They sometimes, however, fight stout battles of gallantry for the females, which battles

are said to take place chiefly upon the water; and they do not strike with the wing as they do when defending themselves, or driving away an enemy from their nest and brood when on the land, they try to drown each other by seizing the neck, and keeping the head under water. They are very hardy and long-lived animals; and their down, or under plumage, is so close and fine, that they are well adapted for remaining on the water for the greater part of their time. When it was the fashion to have things large and rare at the tables of the opulent in preference to things really good, swans made a figure in the bill of fare. They have now, however, been wholly discarded; and besides the regret that we feel that the water should be deprived of birds so very ornamental, there is really very little temptation to kill swans for the sake of their flesh. It is black, hard, and rank, even in the young ones, and the old are too tough for being masticated. The eggs are also not very palatable; and so there is every inducement to leave them in the undisturbed possession of their proper element. Their skins, their feathers, and their down are used for many purposes; but still though these are of considerable value, they are not of so much as to compensate for the loss of the birds. It is of the waters only that they can properly be regarded as ornaments; for when kept in the farmyard they are quite out of their element; and cannot be kept without absolute confinement, unless their wings are so mutilated as to deprive them of the power of flight. But though they pine in confinement, and cannot be made to remain willingly in a state of regular domestication, they can become very tame upon the water, and will readily come sailing in their best style to those who are in the habit of giving them food. There are several species; and one, the black swan of Australia which bears the climate of Britain very well, was long looked upon as a bird impossible to be found. Many of the animals of Australia would have astonished the ancients; and thus it was perhaps only natural that the bird whose existence they held to be impossible should be found in that part of the world.

THE WILD SWAN, whistling swan, whooper, or hooper (*Cygnus ferus*). The bill of this species is semicylindrical, and of a black colour, but with the cere on the base of the upper mandible yellow; the body is white, but with a yellowish tinge on the head and upper part of the hind neck; the irides are brown, and the naked parts of the feet black; the bronchial part of the trachea is very much enlarged and convoluted; the length of the full-grown male bird is rather more than four feet and a half; and the extent of the wings two or three inches more than five feet. The female is less than the male, but of the same colours.

It is highly probable that the notion of the swan being mute while in health, and becoming musical at the approach of death, arose from confounding this wild species with it. The voice of the wild swan cannot certainly be looked upon as very musical; but there is a mournful sonorousness about it, which gives it not a little of the expression of a song of death. It is a dull and solemn *hwoo hwoo*, having what is called an inward sound, though audible at a considerable distance. The voices of birds are all inward, that is, the proper organ of sound is at the bronchial end of the windpipe; but those that trill in clear and sharp keys, evidently modify the sound very much by the action of the throat, the mouth, and the tongue. Such

a bird as the wild swan has very little of this kind of modification; and thus the sound is delivered with all the harshness and depth which it receives from the convolutions of the trachea.

This is not the only confounding that there has been of these two species of swan; for Buffon and others have regarded them as being the same species, notwithstanding the marked difference that there is between them, which is not of the same kind as any change that we know to have been produced by artificial treatment. The windpipe of the white ortami swan has not the same structure as that of the whistling one; and the bill and its cere are not of the same colour. We know of no instance in which the form of the windpipe of an animal, or indeed even the mandibles and the cere of a bird, are changed by the most artificial treatment. The difference in colour, too, that of a slight yellowish tinge upon the head and nape of what is called the wild one, is the very opposite of what we should expect to be produced by artificial treatment, that is, of what is so produced in the case of other animals. A breaking of the colour is that which artificial treatment usually produces; but here the colour of what is considered as the tamed or artificially treated one is the more entire of the two; and, therefore, even setting aside the mere specific differences of the windpipe and the bill, this change of colour, the very opposite to what we invariably meet with when a tame animal is bred out of a wild, is quite against the possibility of an identity in species between these two swans; but, farther than this, the mute white swan has not been subjected to any kind of artificial treatment by which its natural characters or habits could have been much changed. It is not a domesticated bird in any one part of its habits or economy. It does not breed in confinement, it is not fed artificially, and it is put under no particular shelter by which the effect of the atmosphere upon it could be altered. It is among the domesticated animals, that is, it is upon the same grounds with them in some part of the breadth of these grounds no doubt; but it is itself subjected to no artificial treatment; and the best proof of this is, that, in no part of the world where the white swan is to be found, have its colours been in the least broken or changed. Now, in every domesticated animal, the colour that it has in a state of wild nature is the very first thing to give way; and then the perfect colour of the white swan is an unanswerable proof that it is really a bird in a state of nature; and, consequently, those who assert that it has been bred out of the whooping swan, maintain, in fact, that one species of animal may, in a state of nature, and without any interference of art, originate another and different species. Once admit this, and there is an end of all rational disquisition upon the productions of Nature. If one species can, in the ordinary course, and without any interference, originate another species, there could, by possibility, be no rational or intelligible distinction of species at all; for all the distinctions of animals would be broken down, not by external circumstances, but by the very nature of the animals themselves; and were this to be the case, the whole of Nature would be one mass of confusion, to which not one iota of philosophy could be applied.

The localities and the habits of these two species of swans are also quite distinct. The wild swan is a much more migratory bird than the other, and its habitat is found farther to the north, to which it

retreats in the breeding season, whereas the white one remains in the same locality without showing much, if any, disposition to change its abode with the seasons. Now, as the white swan, however more familiar it may be in its habits than the other, cannot in any sense of the word be considered as a tamed or domesticated bird, we must look upon them both as having distinct habits, as well as distinct characters, in a state of nature; and if there are not sufficient grounds of specific distinction, truly we know not between what two animals of the same genus such grounds of distinction are to be found.

The whistling swan is a bird very generally distributed over the northern parts of both the eastern and the western continents. In severe winters they come south in small flocks to the fresh waters near the shores both in England and in France; but it does not appear that they reach the south of Europe, excepting very rarely, and when the winter storms are more than usually general and severe. Early in the spring they quit the more southerly places; and in the longitude of the British islands, they do not remain to breed except in the far south, and then only in a very small portion of the numbers that make their appearance during the winter. We are not aware that any have ever been found breeding on the main land, excepting in that part of Caithness and Sutherland which classes toward the Polar Sea; but they were, once at least, more numerous in the Orkney and Shetland Isles, and some of the more northerly of the Hebrides. In the Faroe Isles they are, of course, still more numerous; but the great body of them must breed further to the north than these islands; for they arrive there, and also in Shetland, in numerous flocks about the month of October, but earlier or later according to the character of the season; and when the severe weather sets in, they diminish in numbers there by breaking into small parties, and moving further to the south. If the winter is comparatively open there, which it frequently is in places but little elevated above the level of the sea, they continue in considerable numbers upon the fresh-water lakes, feeding upon the submerged roots of aquatic plants, which, on account of the stems lying completely down, are very farinaceous in these high latitudes.

As soon as they begin to feel the influence of the spring, they collect their scattered parties, and retire to the regions farther to the north to spend their summer and rear their broods. Vast numbers of them are said to be met with at that season in all the polar countries—in the north of Siberia, of Lapland, in Iceland, in America, especially in the countries near Hudson's Bay, and even in Greenland; though more are mentioned as being met with in Nova Zembla or Spitzbergen. Being chiefly vegetable feeders, they of course resort no farther to the north than the roots and stems of plants are to be met with in the waters; and they avoid mountainous districts, and resort only to those in which there are lakes or rivers of considerable magnitude. On their migratory flights they ride very high in the air, and follow close to each other. The high flight is no doubt taken as a security against the attacks of the powerful falcons of the north; for which the swans, notwithstanding their great size and strength, would be no match, if the falcons were once to gain "the sky" of them. To every thing above it in the air the falcon is comparatively harmless; and the swan has little or no means

of defence when it is on the wing, the stroke of the wing being what it chiefly depends on for its defence against an enemy, and this being but little available when the bird is flying. By taking the sky of the falcon, the swan is thus enabled to perform its migratory flight in considerable safety. The flight of these swans, when they are upon their migratory journeys, is much more rapid than, from the size and weight of the birds, one would be apt to suppose. As is the case with all birds of lofty flight, it does not appear to be so rapid as it really is. This is a point to which it is very essential to attend to in all cases of animals, or indeed of any thing else in motion. The portion of the retina which the visual impression of the observed object passes over is, of course the standard which we have for the measure of its velocity. In consequence of this, its motion appears to be slower than it really is in the very same proportion that its distance is increased, so that a motion at the distance of five hundred yards required to be ten times faster, in order to have the same apparent speed as a motion at fifty yards' distance. This renders it rather a difficult matter for an ordinary sportsman, however expert he may be in hitting partridges or other ground birds on the wing, to hit swans when they are passing over him in their high migratory flight; and unless he takes aim before them, at a distance which can be determined only by experience, he is sure to miss. The weight of swans, and their size, and the abundance of their feathers, causes the wind to have very great influence on the velocity of their flight. Hence they almost invariably go with the wind in their migrations, and wait, or even halt, on their journey if the wind is adverse. Before a stiff breeze, they can make way at the rate of not less than one hundred miles in the hour, so that they are then very soon out of the observer's horizon. But against a wind of equal strength, they can make very little way; and upon a strong cross wind they drift very far to leeward.

The young swans, which are bred in Iceland and the other northerly places, are not able to take their departure the first year. They moult in August, at which time they are incapable of flight; and so the people hunt them with dogs, or sell them with clubs, their flesh being much relished in those countries where dainties are but few.

These birds have acquired a very considerable degree of fictitious interest, and therefore, besides the exaggeration of the musical power of their "sweet voices," there are various other improbable things alleged of them. For instance, it is said that when the frost begins to set in they assemble in multitudes, and keep the water in a state of agitation to prevent it from freezing, while the fact is that all the agitation that swans could produce in the water of a lake would just make it freeze the more readily. It is probable, however, that they break the thin ice, and continue breaking it at the same spot as fast as it freezes, for this is the habit of many animals in the winter.

Though, upon ordinary occasions, the wild swan is a very peaceable animal, and never voluntarily makes an attack upon any other animal, it is by no means deficient either in power or in courage. The angle of the wing is the part with which it strikes, and the motion is so rapid, that the stroke is much more powerful than one would suppose from the mere volume of the striking instrument; but when we consider that the effect of a stroke is made up of two

elements, the quantity of matter and the velocity, and that while the effect increases only as the quantity of matter, while it does so as the square of the velocity, we can easily understand how soon rapidity of motion will make up for any inferior weight in the moving instrument. One-fourth the quantity of matter moving with four times the velocity has an effect in the proportion of sixteen to four; that is, it has an effect four times as great. It is upon this principle that a piece of candle may be shot from a gun or pistol, so as to pass clean through a deal board of considerable thickness. Even this is not all, for the small weapon delivers its effect upon a much smaller portion of that on which it impinges; and in proportion as it does this, the effect of it is also increased. Hence there may be less exaggeration than many suppose, in the allegation that the blow of the wild swan's wing can knock down a hog, or hit a bird of prey, or even a predatory quadruped, in so smart a style, as to make them avoid a second rencontre.

▷ The female swan builds a large but rude nest, very near the margin of the water, but on a place where there is no chance of inundation, and where she can command a view of danger should it approach. From the water she has nothing to fear; and thus, if she finds a little jutting promontory of the land suitable to her purpose, she prefers that, and sits with her head to the land, unless when the state of the weather renders another position more convenient and safe. The eggs vary from four to seven in number. They are very thick and strong in the shell, of a rusty-brown colour, and marked with white blotches about the middle of their length. The incubation lasts for about six weeks. The northern people, as has been said, are fond of the flesh of the cygnets, or young of these birds; but the adults are not relished by them, though much less particular as to the quality of their food than the inhabitants of more favoured climates. They, however, make considerable use of the skins, dressing them with the down upon them, and sewing them together, in which state they form strong and warm garments; or weaving the down into a sort of framing of network, in which state it is almost equally warm, and exceedingly light and pliable. The down, the feathers, and the quilts, are also of considerable value as articles of commerce.

THE MUTE OR TAME SWAN (*C. olor*) is "the swan," by way of eminence; and, though differing from the other in the particulars already alluded to, it is nearly similar in the leading points of its economy. It is rather shorter than the whistling swan, but longer in the wings, measuring about seven feet, or even a few inches more when they are fully extended. The body is rather thicker too in proportion to the length, and it is, upon the average, a heavier bird when full grown. The bill of the mute swan is of a red or salmon colour, with the margins and the basal cere, which swells into a tubercle of considerable size, black; the whole plumage of the mature bird, when on the water in a pure atmosphere, is beautifully white; and few of the living productions of nature are more beautiful than swans, especially when they are upon the small expanses of clear water, which occur in many of the rich little valleys in the south of England. Though a majestic creature in its motion upon the water, the appearance of the swan harmonises best with water which is clear and tranquil, and grasses and green meadows add greatly to the effect.

In a state of nature this species is not so migratory or so polar in the breeding season as the whistling swan. Some of them, especially in the east of Europe

and in Siberia, where the seasons run more into extremes than they do in Britain, are compelled to move southward when the weather is severe; and even in Britain they are sometimes driven from the waters of particular places by the severity of the weather; but where the waters are open they continue on the same grounds for the whole year round, and where they are placed upon ornamental waters in pleasure-grounds, or even in the close vicinity of cities, they show no very strong disposition to shift to more sequestered haunts, at any season of the year. In places that are much frequented they soon become very familiar; indeed they are far from being timid birds under any circumstances. They appear to be quite confident in that power which nature has given them; and, as they have little to fear from enemies, they are not much given to be pugnacious, at least in ordinary times of the year. When, however, they have nests, they not only defend them with great bravery, but attack, in the most resolute manner, any animal that approaches, not excepting man himself. The female is a close sitter during her incubation, which is about the same length as that of the whistling swan; and while the female sits, the male is very assiduous in watching for the safety of the family. He is ready to resist, and by the most vigorous means to repel, every intruder, not excepting his own species, who cannot come within a short distance of the nest without being attacked. Severe contests often take place between the males upon these occasions, more especially if, as is sometimes the case, there is an odd or unpaired male upon the same water. This odd one is not the assailant; for, as he is not in the guardianship of a female and nest, he does not appear to have the same excitement as those which have this

trust committed to them ; but if he is attacked, he is bold enough in his defence ; and we have heard it stated, though we will not vouch for the fact, that if he should succeed in killing or beating off the legitimate possessor of the ground, even after the incubation is considerably advanced, he takes the place and discharges the duties of watchman and protector, with the same vigilant assiduity as the one which he has vanquished.

The nest of the mute swan is very similar, both in place and structure, to that of the whistling swan, but the eggs are different ; they are of a white colour, and vary from six to eight in number. The time of incubation is about six weeks, the same as that of the other species. The cygnets are grey, and do not acquire their full plumage till the second year, and till then they usually keep in company with each other, which they also do with the old birds, until the time of pairing again comes on. The cygnets, while they are in their grey plumage, have very little of the majestic appearance of the adult swans. As articles of food, they are, however, the only ones that are held in much estimation at the present time, and there is probably more of the want of rarity than of that of nature in them. Taken from the water, in their natural condition, they are comparatively of little value ; but, when they are artificially fattened, they fetch a high price in the market. When tame, swans are kept with a view to profit as well as ornament ; their down and the quills of their wings are pulled twice in the year. This is a very cruel operation ; but then, the feathers pulled from the live bird are better than if they were taken from it when dead ; and, if the operation is performed near the time of the moult, and the birds are well fed, it is not so hurtful to them as might at first be supposed. By having this extraordinary supply of feathers to keep up, the working of their system is much more severe than when they have only to supply the natural moult, and therefore they require artificial feeding, in which oats is as good a supply as they can have. Upon small pieces of water, the banks of which are kept trim and free from aquatic herbage, swans require to be fed in the breeding time, and it is of course necessary to give them food in very severe weather, especially when they are frozen out. They are bad walkers ; and thus, when they are shut out from the water, they are but ill able to find their own food upon the land. Indeed, it appears that, if they have not free access to the water, no feeding can keep them in proper condition ; for their plumage gets dirty and ruffled, and they lose all the spirit and the majesty of appearance which they have upon the waters. When in full possession of their proper element, there are few birds so attentive to the state of their plumage as swans. They bathe and play in the water, by casting it all over them, as if it came from a shower-bath ; and then they begin to trim every feather, which they can do on almost every part of the body and wings, in consequence of the length and elasticity of the neck.

No birds are more, or indeed so much, at home on the surface of the water as swans. Their size, and the closeness, and at the same time the tightness, of their plumage, enable them to ride out during gusts and gales, in which few other birds can keep the surface ; and the pure whiteness of their colour, together with the abundance and fineness of their down, render them very independent of changes of

temperature. One of their most conspicuous advantages, however, is the extent to which they can use the wings in sailing along. The hand part of the wing, that is, the portion from the wrist joint, is that which they use upon those occasions, and as the wings are large and concave, and the quills strong, they can go at a rapid rate before the wind without any exertion of the feet. If the progress is to be right before the wind, then the two wings are equally raised, and that, in proportion as speed is required, they are more expanded. The wings of the swan are, indeed, more effective sails than any that we can apply to our craft. The wings of the swan form a sail at each side, between which the current of the wind passes, and thus acts upon them with much more effect than it does upon the sails which we apply to vessels, and which, generally speaking, all draw one way. Equal sails set on the two sides of a ship, and diverging backwards, would be adapted only for going right before the wind, but they would tend much more to the preserving of a steady course than any sails set upon masts in the mesial line of the vessel ; because the current of air passing between them in that line, and of course also in the line of the specific gravity of the vessel, would keep the progress of that centre steadily to the line of the wind. Sailing upon a wind would be a much more difficult matter with this kind of double canvass ; and it is doubtful whether any contrivance of man could give it the variety necessary for gaining the maximum of effect with the minimum of wear and tear in this way ; but it is certain that, with vessels of the present construction, especially with square-rigged ones, anything but the maximum of effect is produced ; and thus they who have an interest in improving the rigging of ships—and, in a country like Britain, it is every body's interest—would do well to study intimately the mechanism and movements of the wings of the swan as it sails upon the water. It can alter the trim of the wings in a style which is truly admirable. By altering the trim of them, in respect to each other, it can not only sail on a cross wind, but absolutely "lie to the wind ;" and it can "wear" or turn without losing an inch of wing. It would be vain in us to hope for such perfection in our sailing craft, unless we could find a solution of the impossible problem of having an engine of human construction so instinct with life as that it could of itself, and without any human direction, obey the circumstances in which it were placed. This, of course, it would be vain for us to attempt ; but still, the mechanism by which an animal is enabled to do this is a subject well worthy of our consideration ; and with the principles of the mechanics of dead matter, which are the only ones that we can apply to guide us, we might make far more of the study of animal mechanism than has hitherto been made. As to motion, that is, motion originated and directed in the air, we need make no attempt, because we must always have a fulcrum to start from equal to the resistance of the medium through which the motion is to be made, and the force necessary for overcoming the exertion of that which we impel ; but when that which we move starts from the earth or the water at each application of the native impulse, and moves partly in the air, we cannot take too many lessons from those actions which nature performs under circumstances nearly the same ; and our lessons here have the advantage of being as pleasant in the acquiring

as they are useful in the application. Of this we cannot have a more delightful instance than in the swan, whether we consider it as rowing, as sailing, or as combining the two together. The waters upon which swans are seen are, in Britain at least, all in very lonely places, and the birds are most out upon the breadth of those ornamental waters at the most delightful season of the year—the green maturity of the season, which is midway between the bloom of the summer and the abundance of the autumn.

White swans cannot be regarded as in a perfectly wild state in any part of the British islands; and the obvious reason appears to be, that there is no part of those islands in a state of wild nature which is at all fitted to the habits of the white swan. It is a bird of such places where there are rivers and lakes with abundance of reeds and the taller aquatic grasses, and other plants which can furnish it with a supply of food at all seasons of the year; and when it is upon the waters of such places, it shows no disposition to migrate, as is shown by the whistling swan; we need not therefore look for it at any season in those northern pools and lakes, to which the other sometimes resorts in the severity of the winter.

But though the white swan cannot be considered as a wild bird with us, so neither is it a tame one. Man has property in it by law only, and not by any attachment that the bird has to him. There are some places of the country where the swans are not claimed by any one as a property; this we believe is the case on the river Trent, and also on some of the waters in the southern parts of the country, where swans as property are more numerous than they are in the north. On the Thames, and on most of the other rivers and lakes, the swans are in general property; and there are some pretty severe enactments against the disturbing of them, or the plundering of their nests. Notwithstanding the disposition to kill and destroy every thing, especially every thing ornamental, which seems to be inherent in the nature of certain classes of mankind, swans appear to be less annoyed than almost any other bird. When on the water they are tolerably safe from any annoyance; and in the nesting time the boys are not very fond of approaching them for the purpose of plundering. They seem to be favourites to a rank considerably lower down than most other birds, for the rest are destroyed without mercy, except when individuals are kept in confinement as a sort of property: and this is in itself a species of destruction to the bird, and has at least but little tendency to improve the disposition of the keeper. In the middle latitudes of European Russia, and of Siberia, swans are much more abundant, and more in what we may consider their natural state, than they are in any part of the British islands; but in what part of the world, or under what circumstances soever they make their appearance, they are always highly ornamental to the places where they are found.

Bewick's Swan (*C. Bewickii*). This species has a considerable resemblance to the common wild or whistling swan, and probably has been often confounded with it; but there are sufficient differences between them, both external and internal, for entitling them to be considered as distinct species. It is a smaller bird than the whistling swan, in the length of the body, the extent of the wings, and especially in the weight, which is considerably less in proportion to the dimensions; the bill is of the same colour,

namely, black in the greater part of the mandibles and yellow in the cere, and the general colour of the plumage is white; instead, however, of the dull yellow on the top of the head and the nape, this bird has the front mottled with rust colour. The chief natural distinction is in the bronchial part of the trachea, which, instead of having a short convolution in this part of the sternum, as in the other, has a large duplicature within the substance, as between the plates of that bone. The habits of this species have been but imperfectly observed; they do not, however, appear to differ much from those of the other wild swans, only as the bird is much more rare in this country, and little adapted for long migrations, it is probable that it inhabits still further to the north in the breeding season, but the fact is not established.

There are various species of swans in other parts of the world, besides those which have been enumerated; but as we know but little of their habits as differing from those already described, a very short notice only will be necessary. The most remarkable is

THE BLACK SWAN (*C. niger*), which is a native of Australia, but has been domesticated in some parts of this country, and appears to bear the climate very well; but it is much more of a tyrant on the waters than the white swan, and will allow no other swimming bird to live in its vicinity. The whole plumage is black, with the exception of the first six quills, which are white; the bill, and a naked space round the eye, are red; the length is about four feet and a half, and the wings rather shorter in proportion than the white swan, but they are broad and strong. The plan and structure of the nest are about the same as those of the white swan, and there does not appear to be much difference either in the food or the general habits. The male is particularly watchful of the female when sitting, and of both female and brood when they are on the water; he not only drives off all other birds, but if any animal, or even a human being, approaches, he lands and marches forth to give him battle at a distance from the family; his wings are raised ready for the stroke, his feathers are ruffled, and he puts on altogether rather a formidable appearance, only it is rendered not a little ludicrous by the awkwardness of his gait, which makes it appear that walking is really more than he can manage, without any toil of battle in supplement to it. It is probable, however, that the strong excitement that he is under is the real cause of this curious waddling motion, and that it helps to "scare the enemy" not "in" but "from" battle. In this country the young are produced about the same season as those of the white swan, and the number in a brood appear also to be much the same. They are of a blackish ashen grey, which continues the whole of the first year. As a curiosity the black swan is all very well, the more especially that it was for such a length of time implicitly looked upon as the impossible bird that was no where to be met with; but it has none of the beauty and grace of the white swan, which must continue to be the favourite as an ornamental bird.

The swans of the tropical parts of Africa and America are smaller than those of the north, and they have the colours in general more broken. We find them, and also in some in the north parts of America, a resemblance to the geese.

THE GAMBIAN SWAN (*C. Gambensis*) will be found described in the article Goose, under the name of

the "Gambian Goose," and reasons will be found stated there why those tropical birds, which have been described by many writers as swans, have been there arranged as a section of the geese. The Canada, or cravatted goose, has also been sometimes described as a swan, but it has the characters of the true goose much more completely than the one now alluded to, and will of course be found in the article alluded to. It does not, indeed, appear that there are any true swans, except the white swans of the north part of the eastern continent and the black swans of Australia; and it is not a little singular that countries so wide apart, and differing so much in all their other living productions, are the only ones that agree with each other in containing native swans.

SWARTZIA (Willdenow). Evergreen shrubs, natives of the West Indies, and belonging to *Leguminosæ*. The species are stove plants, thrive in light loam, and may be increased by cuttings rooted in sand under a bell glass.

SWEETIA (De Candolle). A genus of South American climbing shrubs, bearing diadelphous flowers, and belonging to the natural order *Leguminosæ*. There are three or four species which have been known as *Galega*, *Tephrosias*, or *Glycines*; but renamed as above by De Candolle in honour of the late R. Sweet, F.L.S.

SWEET POTATO, is the *Convolvulus batatas* of Linnæus, and the *Ipomœa batatas* of Poirêt. Its tubers are eatable, and much used in tropical countries.

SWEET SOP, is the *Anona squamosa* of Linnæus, a tropical fruit-tree long known, and frequently fruited in our collections.

SWERTIA (Linnæus). A genus of perennial aquatics, and annual and biennial herbs, natives of Europe, and belong to *Gentianæ*. The *S. perennis* is called felwort in English botany.

SWIETENIA (Linnæus). A single but most valuable timber-tree, a native of the West Indies; the flowers are decandrous, and the plants belong to *Meliacæ*. This is the celebrated mahogany-tree of commerce, of which so much use is made in the fabrication of household furniture. The plant grows well in the stove, and is propagated by cuttings. There is an East Indian species called *S. febrifuga* by Roxburgh, from its medical properties.

SWIFT—SWALLOW. See *HIRUNDO*.

SWINE. See *Sus*.

SYCAMORE, is the *Acer pseudo-platanus* of Linnæus, a well-known timber-tree, long naturalised in England, and much used in ornamental planting. The timber is chiefly used in turnery.

SYLVIA (Warblers, or rather *SYLVIADÆ*, the warbler family). A genus, family, or section, for it has been differently viewed by different describers, of the order *Passeres*, the family *Dentirostres*, and the fine billed division of that family in Cuvier's arrangement. The whole of the slender-billed family, as known in his time, were arranged by Linnæus in one great genus *Motacilla*, or "Wagtail;" but as the mere motion of the tail is not a characteristic from which any useful conclusion can be drawn, it became necessary, after the structure of birds entered into the grounds of their arrangement, to make very considerable alterations, and to subdivide the Linnæan genera into many parts.

In all the family of fine-bills, the bill is slender and in the form of a little style or bodkin, with the tip

sharp, and capable of entering very small crevices in the bark of trees, or pecking out caterpillars from their folds or other dwellings in or among the leaves. They hold, at least in so far as the form of the bill is concerned, an intermediate place between the finches as birds feeding in great part on seeds, and the shrikes as the most ravenous and exclusively animal feeders of the whole order *Passeres*. In those that approach the finches in character, the bill is quite straight, without any notch, and a little depressed at the base; while in those that approach the shrikes the bill is a little compressed at the base, with the upper mandible very slightly curved, and an obscure notch toward the tip. It is not very easy to find a general description which can apply to the whole of this very numerous and diversified species of birds other than that from which the family has been named by Cuvier; and in this we can discover the superiority of that great comparative anatomist and physiologist, drawn as it is from nature alone, without any theoretical basis of human contrivance, over the systems of more recent and fanciful, but incalculably shallower personages, who have not made their systems, as they ought to have done, the mirror of nature; but have made nature the mirror of their systems, or at least attempted to do it, which is much the same. They take up the succession from the *Orioles*, and the *Mænura*, or lyre-bird of Australia; and after proceeding regularly through the different genera, to the *pipits*; and passing over the *Syndactylic* and *Fisirostral* birds, which from the peculiar characters of their feet, their bills, or both, cannot be made to come into the regular series, they merge in the larks, with which the *pipits* have so many points of resemblance that they were once considered as larks. They are thus a regular section of the great succession of birds which may be considered as having the feet with three toes before and one behind, and not in any way decidedly adapted to any one kind of action with those organs.

As there is no established English name for this extensive family of birds, and no scientific one which is expressive enough, we shall give a short catalogue of the genera in this article, referring to such as are more minutely described in other parts of this work, wherever such reference appears to be necessary. There are eight principal genera in the fine-billed family, and, as one of them admits of subdivision into two sections, there will be nine in all for our consideration, and we shall take them in the order in which they are given by Cuvier.

1.—**SAXICOLA** (*Chat*). These are the birds of the family which have most of the character of the straight-billed shrikes. An account of them will be found in the article **SAXICOLA**.

2.—**SYLVIA**. This genus has no appropriate English name, we might perhaps call them the redbreast genus, as our little familiar favourite, the common redbreast, is the typical bird; but then all the others have not red breasts, though they agree with the redbreast in characters which are more important. The birds of this genus have the bill a little more straight at the base than the chats, indicating that they are not so exclusively insectivorous in their feeding, and some of them, at least, are stationary even in countries far to the north; whereas the chats are migratory, and depart when the season of insects is over. Their food, in the warm season, consists of insects and worms, but in the winter they subsist in great

part upon wild berries, seeds, and other vegetable matters. Indeed, at that season they are very miscellaneous in their feeding, and pick up all sorts of scraps, both animal and vegetable. They are all solitary birds, never appearing in flocks, even in the most severe weather, when almost all the smaller birds are not only social in their own species, but mingle freely with others, without the slightest signs of hostility. The members of this genus, on the other hand, are never seen even two in company, for though several may be seen near to each other, there is never the slightest indication of any concerted movement or recognition of the one by the other. Even when they pair, they are strictly *cryptogamous*, for the pair are not seen together. They nestle in holes of trees or of walls; and at that season they are not much seen even in the places where many of them nestle. When seen, they are generally skulking about among the trees; and even the song of such as breed in the woods is but very rarely heard there. But though they are thus solitary in their habits, as regards their own species, and indeed all other birds, they are by no means timid or retiring at those times when the purposes of nature do not call them to the depth of the forests. On the contrary, such of them as winter where the season is severe, are among the most familiar of birds, and not only approach houses, but do not hesitate to enter them with a boldness displayed by very few birds. Even in the breeding season, their skulking appears to have much more reference to the finding of food, than to any timidity or alarm; for though they move about and are careful enough to be out of the way of danger, yet they never become agitated, or fly off to any great distance, they merely shift about so as to get the screen of the tree, or other cover, between them and that by which they happen to be disturbed. They are also of a bold and pugnacious disposition, and when in a state of confinement they attack and vanquish birds larger than themselves. Their songs are not so varied and melodious, or given in such volume and with so much energy, as those of some others of the family; but they are in general sweet, and the resident ones, which quit the woods in the winter and resort to the vicinity of houses, sing after their arrival and again before their departure, or if the season is mild and open they sing occasionally throughout the whole of it. When they sing, however, they never come quite close to houses, or attempt to enter them, for the same severity of the weather which drives them to this familiarity, renders them perfectly silent. The species which Cuvier has included in the genus, differ a good deal in their external appearance, especially in their colour: but there does not appear to be any difference sufficient for warranting the further division of them into genera, though that has been attempted by some of them who are in more than an ordinary degree system-smitten.

Redbreast (S. rubicola). In the late autumn, the winter, and the early spring, this is one of the best-known of birds, and almost every one knows it, without requiring any description; but in summer its habits are much more obscure, so that doubts have been started whether it is or is not a migrant. That it does change its ground with the seasons is true; but then it is only a little way, namely, from the close vicinity of the house to the nearest copse. Some indeed may shift from the cold districts to the warm when the cold weather sets in; but there is

no reason to suppose that any of them take long journeys, and especially that they pass beyond sea. They are at all times birds of short flight, and very rarely seen upon the wing unless in shifting from tree to tree, or between a tree and the ground.

Although, when they are driven to extremities by the severity of the weather, the redbreasts are the most familiar of birds, yet they have the solitary habits of the genus perhaps more strongly than any of the other species. When they are upon the breeding grounds they are very jealous of each other, and if one happens to approach too near the domicile of another, a battle is the result. Even the young of the year, when they come to the neighbourhood of houses, do not come in society; and it is said that two birds of different broods never perch on the same tree, though this is obviously a point which it is difficult, and even impossible, to ascertain with any thing like certainty.

Unless it be in seasons of uncommon severity, or in climates where the winter is very prolonged, the redbreast quits the vicinity of human abodes, and betakes itself to the woods, sometime in the month of March. It does not depart, however, until there is some action of the spring in the places to which it retires; and if the storm returns with severity, the redbreast comes back along with it. It prefers those places of the woods and copses which are humid, or near marshy grounds, because these abound much in insects and in earth worms, which are the true staple articles of its summer food. The nest is always upon or near the ground, under natural cover if possible; and when this cannot be had close enough, the bird is said to make an artificial concealment with withered leaves. This is what is alluded to in the old ballad of "The Babes of the Wood," though there the bird is represented as covering not its own nest but the bodies of the deserted children; an office which, of course, it would not perform. A hole in the ground, or in a wall, is sometimes had recourse to, when the cover of trees or bushes cannot be had near the surface of the ground. The nest is formed of dry grass and withered leaves, and finished in the inside with finer vegetable substances and feathers. The eggs, which are of a dull whitish colour, marked with waved lines and spots of ash and rust colours, vary from four to seven in number. During incubation the male sings, but by no means loudly or so as to be heard at any great distance from the nest, so that his pleasant though feeble notes are drowned by the more tuneful voices of the grove, which are at this time pealing in full orchestra. As is the case with all the fine-billed birds, the young are in the nest for a considerable time; and the parents are very assiduous in feeding them.

Their food, and indeed that of the whole genus, is not the same in the breeding season as that of the genus *Curruca*, or the true warbler. These last do not of course refuse full grown insects if they can get them; but they do not regularly hawk for such on the wing, their food consisting much more generally of caterpillars. The robin preys much more upon the full grown insects when they are beating about to find among the leaves suitable places for depositing their eggs. In this way, the good which the birds of this genus, and especially of this widely distributed species, do to the woods and copses is very great; for the capture of one parent insect ready to deposit her eggs may be reckoned equal to the cap-

ture of a thousand caterpillars, and the caterpillars which the birds pick from the leaves, and other parts of the trees, have always done some mischief before the birds can find them, generally before the sylvan warblers of the summer betake themselves to the groves, or even before they arrive in the country.

But the redbreast does not confine itself to the insects which it captures on the wing, or by hovering about the leaves till its opportunity arrives; it descends to the ground, where it captures multitudes of worms and ground larvæ, and also the mature of these,—Gaffer Long-legs for instance, and the other *tipulæ*, which are so destructive to the rootlets of herbaceous plants, and also the small jumping beetles which destroy the seed leaves of turnips and other dicotyledonous plants.

Thus, when the robin, having sung the vespers of the one year, and the matin song of the other, amusing us with the familiarity of its manners during the pause of nature between, leaves us for a season, and the performance of its own seasonal purposes, it does not quit our service; but works as diligently for the conservation of the vegetation of the grain, as it does for that of the garden and the home shrubberies during the winter. Indeed the whole of the *sylviadæ* are great conservators of vegetation, protecting it from foes which no human skill or labour can reach, and exerting themselves with an assiduity which not the most zealous and persevering of the human race could by possibility undergo. Try to pick the aphides, one by one, from a single rose-tree, or the caterpillars from a single cabbage or cauliflower, which has been planted in the wrong soil or situation, and he will have some idea of the labour which is performed by the fine-billed birds. Then it appears as if nature had endowed them with their sweetness of song, in order that men might be melted by their melody, and so spare them that they may do good. This is the fact in many more cases than we are aware of; and there are few facts in the whole range of nature that are more delightfully instructive. Those in the animal kingdom are, of course, the most striking, because animals themselves draw the general attention more than the productions of the other kingdoms of nature. Now it will not fail to strike any one who devotes but a moment's attention to the subject, that those animals which do not in any obvious way work for the good of man, always retire from places as they become peopled and cultivated; while those that are eminently useful not only stay, but increase in numbers, and follow cultivation into places in which they were not to be found so long as those places were neglected. Thus, in Britain, while eagles and ravens, and also the wild mountain game, and the long-legged fishing or scavenger birds by the waters, are all very much confined in locality and diminished in numbers to what they once were; on the other hand, the field and woodland game birds, the partridges in the fields, and the pheasants in the copses (though the latter are imported birds), have multiplied greatly; and the warblers have extended into districts in which they were formerly unknown. Now, in all instances in which such changes take place in the children of nature adapting themselves to the progress of art, we may rest assured that the animals which diminish in numbers or disappear, are not wanted in the state of culture, and would be injurious if they were to remain in numbers. Those again which remain

where cultivation extends and improves, always have some useful office to perform, whether we understand the nature of that office or not. Even they may be in excess, however, beyond what is required for good, and then the surplus must do mischief; but this is a point upon which we cannot, in the nature of things, obtain perfect information; and therefore we must not come to any positive conclusion respecting it. Of the general good done by the *Sylviadæ*, there can, however, be no doubt, and there can be as little as to the particular advantages of the summer labours of the redbreast.

But its winter labours are scarcely less valuable. It comes to the gardens, orchards, and vineyards early in the season; and although it plunders the grapes to a considerable extent there is hardly any thing in common gardens and orchards to which it can do much harm. Its bill is not formed for cutting and dividing large substances; and therefore the leaves of the mountain ash and other analogous trees, none of which are of much value to man, are the chief subjects of its vegetable plunder. Vegetables, indeed, are a secondary object with it at all times, and it never has recourse to them, if it can find insects or worms, even at the expense of far more labour than the vegetables would cost. This is the great foundation of its value in the garden and near the house in the autumn, the winter, and the early spring. It is one of the most industrious of birds, the first to begin its work in the morning, and the last to give it up in the evening.

Its early arrival in the autumn is of particular value. It comes long before the air is freed of winged insects for the season; and it watches them with assiduity, and catches them with certainty, when they resort to those places where they deposit their eggs. It is understood that the young birds are the first to appear near houses in the autumn, and that they break into song, in consequence of the food which they then eat, and the temperature of the season jointly bringing upon them a sort of forced act of that energy which is to come into full vigour and exercise in the spring. Be that as it may, their song in the autumn is exceedingly pleasant; because amid the decline of the year it sings of hope and prophecies that the spring will again return.

The natural cause which brings it so constantly and so closely to the dwellings of mankind, is the number of perfect insects which are kept alive by the artificial heat of such places. These are chiefly, if not wholly, females; for the males of insects are something like the anthers of flowers, they perish as soon as the function for which they are appointed is performed. But the females have a longer duration: they have the eggs to deposit; and, if no casualty overtakes them, they do not perish until that is performed. In countries where the seasons are very marked, the cold often comes upon them before the eggs are laid; and it appears that they are under some special protection of nature while charged with this important trust. When the cold overtakes them they become dormant, until they are aroused to activity by the return of warmth. Some of them, as for instance the bees and wasps which form annual colonies, remain in this dormant state all the winter; but there are many others which habitually deposit their eggs and perish, of which a considerable number become dormant in a temporary way, but are ready for being called into activity by any natural or even artificial increase of temperature. The redbreasts are not only on the

alert to capture those insects when they appear on the wing or in motion, but search for them in the chinks of walls, the clefts of trees, and all other hiding places in which they are likely to be found. The insects which are so captured by the birds, are all matured females ready for depositing their eggs, and as we have said—and it is an under statement—the destruction of one mature insect in this state is equivalent to the destruction of a thousand larvæ, the advantage which the redbreasts give at this season, are almost beyond the power of calculation.

Besides its direct usefulness, which is thus very great, there is something very pleasing in the familiarity of the redbreast. If it is fed with crumbs of bread, or little bits of meat in the window sill, it will not only return while the storm lasts, but it will, as is said, come back year after year to the very same place. In the cottages of the upland places in the north, where there is no regular chimney, and where in consequence it is often necessary to keep the door open in order so to confine the acrid smoke of turf and wood to the upper part of the house as that the people may be able to breathe, the robin will, after a few pauses and lingerings in the porch and at the threshold, come hopping on the floor, and even show the same familiarity as if it were one of the family. This is a little curious; for the bird which is thus familiar with man and his dwelling, and which will perch on the shoulder of a person sitting still, or on the back of a dog lying by the fire, has less familiarity with birds in general, and with those of its own species in particular, than almost any other that can be named. Innumerable anecdotes of it have been printed, and there is probably no person who has been familiar with the country, or even with the straggling outskirts of towns, who could not, if so inclined, add to the list. The progress of its familiarity is well told in Thomson's "Winter"; but the tale must be too familiar to every body for needing to be repeated. We shall only allude to one instance, in which the bird appears to have taken up its regular abode in the house for the winter, and yet returned to free nature in the spring. In November 1788, a redbreast, shivering with cold, tapped at the window of M. Gérardin. The window was opened, and the bird perched with the utmost confidence on the back of an elbow chair near the fire. When it had recovered from the effects of the cold, its first occupation was to attempt catching the few house flies which had been awakened from their dormancy by the warmth of the apartment. It was fed upon crumbs of bread and small shreds of boiled beef; and so well did it like its lodging and board, that it not only remained during the winter, but sung its hymns of gratitude as cheerfully every morning as if it had been perched upon a twig in the spring. It was particularly familiar with M. Gérardin; and although it did not actually assist him in his studies, it amused him while engaged in them. It perched upon his desk, and sometimes on his left hand while he was writing; in short, it was more familiar and at home than the majority of birds which are reared from the nest with the greatest care. In all this, however, there was not the slightest degree of attachment, but merely a very powerful instinctive attention in the bird to its own personal comfort—which is one of the most necessary, and therefore one of the most powerful, instincts in all animals; for when the season came round, and the impulse of nature called it to the woods, it flew away and returned no more.

If circumstances render it necessary for the redbreast to build its nest and rear its brood near the habitation of man, it shows the same attention to its own occupation, and the same indifference to what they may be doing in its close vicinity. They may work, and hammer, and make as much noise as they please, without in the least disturbing the bird, if they do not invade the place of its nest. Indeed, it hops about near them, and scrutinizes with curious eye, as if it devoted a part of the leisure of its own active life, in superintending and seeing that they perform their task with equal assiduity.

This familiarity and curiosity often costs it its life; for they make it very apt to run into the snares of the bird catcher. In Britain this is rarely taken advantage of, because though redbreasts are very common they are not very numerous at any particular spot; and the only small birds that will repay by their flesh the trouble of catching them in Britain, are those that flock numerously on the fields in the winter; and even they are attended to in particular places only. But it is different on many parts of the continent with little birds generally, and with the redbreast in particular. In many parts of France, and in particular in the valley of the Moselle, redbreasts are very numerous in the autumn, being attracted in great numbers to the vineyards. The catching of them is there a considerable trade. They are mostly carried to Paris, where they are held in very high estimation by epicures; but they must be carried very quickly, as they lose, in four and twenty hours, the flavour for which they are so much esteemed when recent.

The *Blue-throated Warbler* (*S. suecica*) has been already described at some length, in this work, under the name *BLUE-BREAST*, and with the synonymes of "Fantail" and *Pandicilla*. We have little to add to the description given in that article. The bird is far more numerous in the north of Europe than the redbreast, and it is found in much higher latitudes, and at greater elevations upon the mountains. It is much more of a marsh bird than the redbreast, and not quite so much of a woodland one. Its nest is very often in the cover of the dwarf birch, or the heath, and generally among the wild willows which creep along by the sides of the mountain-pools, rather than in the woods properly so called; and in winter, though some of the birds descend to the low country, the greater part migrate to the south. It has not the familiar habits of the redbreast. In those situations where it has only low and creeping bushes as a cover to the nest, with no trees in the neighbourhood, it does not, at all times at least, sing from the perch, but rises to a small height in the air, and sings hovering on the wing. Its natural song is sweet, and contains a very considerable number of modulations; and, from one or another of the birds, it is heard all the night long—we speak of Lapland, where the night has no darkness. It is then that its song is most pure, for it is a great mimic, and when the other birds around it are in voice it imitates them all in succession. The Laplanders are very loud in praise of its musical powers, probably because song-birds are but few there; and they may prefer it, as they do, to the nightingale, upon the same principle that the Highlandman gave preference to the hooded crow, one of the most husky-voiced birds in existence, over the parrot:—"She speaks better Gaelic in the Hebrides than ta creen dtóo that will no be there." It is rare in middle Europe, and still more so in the

south; not appearing even in Germany, except in the winter, or in Britain, except as an exceedingly rare straggler on the eastern coast. Insects are its chief food in the summer, and wild berries in the winter.

The Redstart, Red-tailed, or Brown-tailed Warbler (S. phænicurus). This bird is better known, and therefore more interesting, in the middle and more southerly latitudes than the former. It has been made the *name bird* of one of the modern genera, by raising the specific name *phænicurus* to generic honours. Now, even as specific, this name is not very happy on various accounts. In the first place, the colour on the bird is not red but reddish-brown; in the second place, this brown is not so red on the tail as it is on the lower part of the back and rump, and on the fore part of the belly; and in the third place, the tail-feathers are not wholly reddish-brown on the upper side, the side from which the colour of the tail ought to be described, if it is to be described from colour at all. But, besides these objections, there is a more weighty one, namely, many other birds have the tail much redder than this one; and thus, though it is the most red-tailed of Cuvier's *Sylvia*, and therefore correctly enough styled the *phænicurus* among them, the pointing of it out generically as the red-tailed bird is ludicrously absurd, just as calling the blue-throated warbler *Pandicilla* is "flat burglary as ever was committed" on the tail of the peacock, worse than "accusing the lady Hero wrongfully."

The red-warbler or red-robin (for one or other of these seems to be its most appropriate English name) is a bird of rather less than half an ounce in weight, and five inches and a half in length. The bill and feet are black; the irides hazel; the front white; the top of the head, back of the neck, and upper part of the back, bluish-grey; the cheeks and throat black, the black extending on the sides of the neck and the upper part of the breast; the rest of the body red-brown, which is deeper on the lateral feathers of the tail, and the two middle feathers of the tail and the quills blackish-brown.

As a British bird, this species is only a summer migrant, a common one in the south of England, and along the eastern part of the valley of the Severn; but more rare in the north-east, and very rare in Scotland, occurring only in the counties on the Solway Frith, and the valley of the Clyde, and some parts of the Lothians, not frequently in these. Like many of the summer migrants, it is not found in the south-west of England, where indeed we could not expect to find those birds which migrate by short flights, which appears to be the case with all the fine-billed migrants of whatever genus. Syme says, he has "frequently met with it in the neighbourhood of Edinburgh. Though a very shy bird, it often approaches and builds near the habitations of man, and constructs its nest in places that we should scarcely expect so timid a bird to select for that purpose. At Craigcrook Castle, near Edinburgh, we found its nest in a hole of a wall, close by an old gateway, through which people daily pass to the castle; it was placed within reach of the hand from the ground. These birds often haunt gardens, orchards, and shrubberies; but they also frequent solitary situations among rocks, crags, and woods, where they build in the crevices of dangerous ravines and precipices. Though wild and timorous birds, they are often found in cities, but

always selecting the most difficult and most inaccessible places for the important work of incubation. If the eggs are touched by the hand, unless the hen has sat for some time, she will forsake the nest and build again."

We have quoted this passage, which has been quoted by others, not certainly as recommending the soundness of the doctrines which it contains, and still less with any intention of criticising the style, though certainly it is very open to criticism. We are aware that Mr. Syme's observations were well made and faithfully reported, because he looked upon nature with the eye of a very clever painter, capable of discriminating the most minute details. But he has totally misunderstood the character of the bird, and therefore his conclusions are the very opposite to those that naturally follow from his premises. The nestling in the gateway and in the cities are no characters of a "timid" bird, whatever they may be of a bird of hiding habits, and solitary as regards other birds, whether of its own species or of any other. This is farther corroborated by the ease with which the bird can be tamed, and the readiness with which it recognises those that feed it. Its disposition, as well as all the essential points of its organisation, are the same as those of the redbreast; and the chief difference is in latitude, and in the season of the haunts. In those parts of Britain to which the red-warbler comes in any considerable numbers, it changes guard with the redbreast, occupying in summer nearly the same places which the redbreast occupies in the winter, and performing services not very dissimilar. This, by the way, shews us the great superiority of Cuvier's arrangement of animals according to their general structure, over even the mere species classifications of those who first make the system and then try to make the animals fit it; for if ever there were two birds with distinctions sufficiently specific, and generic characters identically the same, the redbreast and red-warbler are they.

This bird does not, in general, inhabit so near the water, or so much in the copse, and feeds much less upon worms, or any other prey that it can hop after on the surface of the ground. But the red-warbler hops much more up and down, for short distances in the air, than the red-breast does, and it is for the purpose of enabling it to do this that it has the more powerful action of the tail, and has the tail larger and stronger in proportion.

Buffon called the red-warbler "the wall-nightingale," and the name has been retained by many of the French describers, who, like our own, have often fully as much penchant for the *magnifique* as for the accurate. The song of this bird is a sweetly plaintive little song certainly, but it has not a touch of the brilliancy and heart-thrilling song of the nightingale. Besides, it is a morning song in its finest effect, and not begun till that of the nightingale ceases. It is a bird of holes and corners, but it is a very pretty bird; and it is a bird of romantic places. It comes to us in the middle or the latter part of spring, and takes its departure about the autumnal equinox. The eggs are numerous, amounting to six or eight; and, as is the case with the rest of the genus, the young continue long in the nest, and require a great deal of feeding. All the birds, indeed, which come to sing to us in the summer, come also to work; and they reprove those human beings who neglect the more important duties of their situations for empty for-

mality and idle song, a habit to which the vain and half-educated are but too prone. The following passage, from "Sweet," is of value, but we omit his inferences:—"In confinement it soon becomes very tame and familiar, and will be much attached to the person that feeds it; if brought up from the nest, it may be made to sing any tune that is whistled or sung to it. One that I was in possession of some years back, learnt the Copenhagen waltz, that it had often heard sung, only it would sometimes stop in the middle, and say *chippee*, a name by which it was generally called, and which it would repeat every time that I entered the room by night or by day. In winter it would generally begin singing in the evening, as soon as the candle was lighted, and it would sing as late as eleven o'clock at night. In spring, when it first arrives in this country, it mounts to the top of the loftiest trees, where it will sit and sing for hours, beginning in the morning at day-break."

The *Blue Robin* (*S. sialis*), an American species will be found described as the *BLUE BIRD*, to which article the reader is referred.

The *Black Redstart*, or *Blue Robin* (*S. tithys*), is nearly of the same dimensions as the common redstart, but different in colour and in geographical distribution. The upper parts are of a bluish ash-colour; the cheeks, the space between the bill and the eye, and the throat and breast, are black; the belly and flanks are deep ash; the middle of the under part, between the black and the ash, is white; the under tail-coverts, and the rump and upper coverts of the tail, are bright red; and the two middle tail-feathers are brown, with red margins; the greater coverts of the wings have white borders; the first quill is short, and the fourth and fifth are the longest in the wing. The female has the upper part dull ash-colour; the under coverts of the tail reddish yellow; and the rump and upper tail-coverts dull red. The young of the year have a good deal of resemblance to the female, only the ash-colour on the under part is not so bright. This species has occurred in Britain as a straggler, but it is exceedingly rare, and, in fact, one of those birds which it would be in vain to look for in any part of the country. Even on the continent it is a rare bird, at least in those countries where the habits and characters of birds have been much attended to. It is more common in the south of Spain, we believe, than in any other part of Europe, and we may presume that its habits are not very different from those of the redstart; but we have no information to be depended upon respecting this subject.

In the bluebreast, the common redbreast, the redstart, and the black redstart, we have a succession of four species of birds occupying, as their principal habitats, four zones in latitude, beginning at the extreme north of Europe, and terminating at the extreme south, but alternating less or more with each other in all the middle latitudes. On the continent those blendings are much greater than they are in England, or all the birds are of comparatively short flight. We have the one which is at each extremity of the series only as a very rare straggler; the most northerly of the intermediate ones as a common resident, but shifting within the country with the seasons; and the most southerly of them only as a summer visitant in the more southerly parts of the country. There are not many birds which keep up so gradual and regular a series over such an

extent of latitude, and at the same time have their generic character so clear and definite.

There are various foreign birds which have a considerable resemblance to these, but little is known of the majority of them further than as museum specimens, so that they have little or no interest for the general reader.

3. *CURRUCA*—warblers properly so called. These are the true sylvan songsters, and the birds of sweetest notes that are known. An account of them will be found in the article *CURRUCA*, in various other articles referred to from that one, and in the article *NIGHTINGALE*, so that more need not be said of them here.

4. *ANTHUS*—Pipits. An account of the leading species of these will also be found in the article *ANTHERS*.

5. *REGULUS*—Crested Wrens. These are very small, but exceedingly energetic birds, differing in the form of the bill, and in some other characters, from the more conspicuous and typical birds of the family, but still they agree with the majority in their leading habits. The bill, instead of being cylindrical to near the tip, as in the others, is conical, converging to a very fine point, and when it is seen from above, the outlines of the sides are concave, a form which gives it considerable stiffness, notwithstanding its very small size. These birds are accurately known only as European birds; indeed, their dimensions are so small, and their usual habitations so far out of the way of common observation, that they are but seldom seen. We shall confine our notice to these two species.

Golden-crested Wren (*R. auricapillus*). This is the smallest, not only of the British, but of all European birds. The average weight is only about eighty grains troy, so that it would take seventy-two of the birds to weigh a pound. The length in the feathers is about three inches and a half, and the stretch of the wings about five inches; but, when the feathers are taken off, the length of the body does not exceed an inch. It is a very handsome little bird. The upper parts are green, clouded with ash-colour on the hind part of the head and neck; the forehead, the chin, and a space round the eyes, are whitish; the under parts are brownish-white, paler on the middle of the belly, and with a slight tinge of yellow there; the quills are dusky, with greenish margins, and the secondaries have a black hue on the base, above which there is a white one on the coverts; the tail is a little forked at the extremity, and composed of dusky feathers with greenish yellow edges. The most remarkable character of the plumage, however, is the crest on the head. It is longitudinal along the top of the head, and composed of two double rows of feathers, a little distant on their bases, but inclining toward each other at the tips; the external ones on each side are deep velvet black, and the internal, which are longer, and rise over the others, are bright golden yellow, so that the crest, seen sideways, appears like a golden coronet on a black chapeau. The contrast of the two colours is particularly fine. The female has the crest much less prominent, and the young are entirely without it till after the first moult, which takes place in the autumn.

The crested wrens afford a very forcible illustration of the absurdity of associating energy and power of endurance with mere quantity of matter, as we are but too apt to do. Those who fall into this mistake

would be very apt to imagine that this delicately-formed little creature must be the feeblest of all the birds of Europe, and confined to sunny climates and flowery banks. But the very reverse of this is the case. The raven himself, generally as he is distributed, and able as he is to bear the storm, is not more hardy than the golden-crested wren, and the labour which he has to perform is far less severe and incessant. He finds large prey, and, having gorged himself, he dozes, and he at all times uses the wing as little as ever he can, except as a parachute to soften his coming to the ground when he hops. This little bird, on the other hand, is almost incessantly on the wing, beating about among the buds and leaves, hanging by the feet in all sorts of positions, and capturing minute insects and larvæ with wonderful adroitness, but always with the wings ready to act and float it speedily through the air to any new part that he may wish to occupy. In summer it is exclusively a forest bird in most places; but, as it inhabits to the full extent to which the forests reach in the high latitudes of the north, it is sometimes found in lonely bushes. It occurs in the wooded districts of the whole range of Europe, and also of Asia, being met with in the latter quarter from the woods nearest to the Arctic Sea to the woods of India, though it is not to be met with in the central deserts, or anywhere in places of an arid character. It is also found in America, though there, according to Wilson, it is rather larger in size than it is in Europe; and, indeed, the one which he describes as being a common migrant in the United States is, in all probability, the other species, the fiery-crested one; but there is little difference between them, except in the colour of the middle feathers of the crest, the shade of colour on the back, and the size.

These birds are very numerous as well as very generally distributed; and in places where they migrate they appear in great numbers on the middle grounds of their range during the autumnal months. With us in Britain they are found in most wooded places, and they do not appear to have much of any kind of migration even within the country, except a migration such as that which the redbreast has; namely, to the neighbourhood of houses in very severe weather, and to the wood and the copse at other times. It does not, however, come to the close vicinity of houses so early or so regularly as the redbreast, neither does it continue so long there, or enter the house in search of food, though it is any thing but a bird of shy disposition. It is a bird of much more resource than the redbreast, adapted for seeking its food at the tips of those slender twigs which would not bear the weight of any other bird. Its conical and keenly-pointed bill, too, is admirably adapted for digging into the crevices of the young bark, or the hybernacular scales of the young leaves, and bringing out any larvæ or insects that may be lurking there. The pine family are very liable to have the terminal buds attacked by insects, whose punctures let out the substance of the tree, which, instead of swelling the buds and producing shoots, falls in an unseemly powder upon it; the tree, though it does not die immediately, and may stand half living, half dead, grows no more. This most commonly happens in trees which have been only a few years planted where the soil is too thin and dry; and, if they have been once attacked, there is no alternative but to grub them up, for they never recover. The writer of this article has

seen a plantation of Scotch fir which, having suffered an attack of this kind, remained more than twenty years without increasing a single inch in height; and indeed the progress seemed to be that the life of the tree went out branch after branch, the lateral branches continuing to make shoots of normal length, just as one may see in a peach-tree attacked by the aphid, until they were extinguished one by one.

The points of the twigs of these trees can scarcely be reached by any other birds; and thus the crested wrens, small as they are, are of no little use in the pine forests; and we find that these forests are their chief places of resort, though they are not confined to them, and quit the more northerly ones in the winter. They are also partial to oaks; and as the oak is never found in those very cold and upland places where the pines are in general most abundant, the birds remain in them during the winter, which is the proper season for observing them, as in summer they are concealed by the leaves. The male is in song only in the spring, and the song, though not disagreeable, is feeble, so that it is not heard at any distance, and can be barely heard at the foot of a lofty tree when the bird is near the top. The nest is elaborately constructed with moss or lichens, formed and matted together with hair or wool, and lined with small feathers. It is very warm and compact, but without any dome, the entrance being at the top. The eggs are rather numerous, being from six to ten or eleven, of a white ground with a tinge of pink, scarcely marked with any clouds or spots, but becoming gradually darker toward the thick end. They are so small that it takes about fifty of them to weigh an ounce. The parent is very attentive in feeding the young birds, and continues her maternal care under circumstances which evince an exceedingly strong attachment. A remarkable instance of this is mentioned by Colonel Montagu from his own accurate observation. The pair had built their nest on a fir-tree in his grounds; and, though the male sung regularly during the incubation, he ceased as soon as the young were hatched. This is the case with almost all birds in which the male takes any concern in the rearing of the young; but the notion that song birds teach each other was not then exploded, and so the Colonel took the nest and young when six days old, and placed them in the window of his study, with a view to ascertain the fact, and to observe the mode of schooling, if such there should happen to be. The male never uttered any sound during the course of the experiment, except his chirping call-note when the female came in sight; but the economy of the birds was well observed. When the nest was placed outside of the window, the birds came readily and fed the young ones; after this, it was placed inside the window, and again toward the opposite part of the room, the window being left open. In both situations, the female came fearlessly to the nest and fed her little ones; and the male accompanied her to the outside, and waited there till she came out; at first he appeared with food in his bill as well as the female; but after a time he brought none, but merely attended his partner. One part of this is so characteristic, that to abridge it would be injustice both to the observer and the birds. "The female would feed them at the table at which I eat, and even when I held the nest in my hand if I remained motionless. But on moving my hand one day, while she was on

B B B

the edge of the nest, which I held in my hand, she made a precipitate retreat, mistook the open part of the window, knocked herself against the glass, and lay breathless on the floor for some time. However, recovering a little, she made her escape, and in about an hour after I was agreeably surprised by her return, and she would afterwards frequently feed the young while I held the nest in my hand." Her assiduity in feeding the young was perfectly astonishing, and gives us a very striking idea of the immense labour that some birds must undergo. "The visits of the female were generally repeated in the course of a minute and a half, or two minutes, or, upon an average, thirty-six times in an hour; and this continued full sixteen hours in a day, which, if equally divided among the eight young ones, each would receive seventy-two feeds in a day, the whole amounting to 576." Each feed was about a quarter of a grain, so that each of the young had about eighteen grains in the day, or not much less than a fourth of the weight of an old bird to each of the young every day. This female was as attentive to cleanliness as to the supply of food, and bore her severe labour with the utmost cheerfulness. The labour was of course much more severe than if the nest had remained in a state of free nature, for in that state the male would have borne a part, probably nearly the half, though from the fact of his not venturing into the room it is evident that his attachment to the young was weaker.

When the winter sets in severely in the countries which are covered with woods, both to the north and to the south of the Baltic, these little birds take advantage of the wind, and migrate southward in great numbers. They are, however, much more at the mercy of the wind than birds of larger size, even supposing the specific gravity, or weight, bulk for bulk, to be the same in both. This is a point which is worth knowing, though it is one which is generally overlooked; supposing the forms of two birds to be similar, and their specific gravities the same, then the weights are as the solidities or cubes of the same dimension, while their resistances are as the squares. For instance, suppose two birds the same except in bulk, and the one twice as long as the other; then its weight as resisting the action of the wind will be eight times that of the small bird, while the effect of the wind upon it will be only four times that on the small bird. Thus the bird which has double the dimensions has double the advantage; and generally the power that birds of equal specific gravity have to bear up against the wind is according to their dimensions, supposing that they are similar in form, and without any reference to the power and structure of their wings.

Small birds are generally, however, much more disadvantageously adapted to the wind than this. Thus making allowance for the greater length of tail, the golden crested wren is about one-twelfth the length of the golden eagle, and thus the purchase of the wind on the eagle is 144 times as much; but the resistance of the eagle is 1728 times as great as that of the wren; and therefore the eagle, without regard to the structure of her wings, has twelve times as much power in the pursuit as the wren. This is as against the wind; for with the wind the advantage is exactly reversed, and will help the wren forward with twelve times the energy that it helps the eagle. Flying on a side wind, the wren will make more lee way than the eagle at all

angles to the wind; and if the wind is nearly dead against them and blows a gale, they are driven before it like chaff. Selby mentions a case of the wreck of an immense number of golden-crested wrens by a strong gale in the autumn of 1822. The wind was first at north-east, which must have caused them to make lee way westward; and then shifting to south-east, it took them a-head and drove them on the coasts of Northumberland and Durham, along the whole line of which they extended. It is by no means unlikely that a fresh colony of the birds may come to Britain from the northern parts of the continent of Europe every severe winter; but whether they usually return back again to the north, or stay in whole or in part to increase our home stock, has not been, and probably cannot be, ascertained with any certainty.

The fiery-crested Wren (R. ignicapillus) is by no means so common as the other; and it is very lately added to the list of British birds, and was so added by the ornithological talons of a cat. The whole tabby race have been long known to possess a great natural genius for ornithophagi, so much so, that if the cat can find birds enough in the shrubbery, the mice may lord it in the larder as they please; but just as the march of intellect, and the effects of education, converted the natural cannibalism of man into the noble science of war, in which the hero does not kill his fellow man for his own eating, but for the glory of a royal master, or the exaltation of a grateful country, even so a most famous tabby in the possession of an intelligent and amiable naturalist at Swaffham, was schooled to capture birds, not for her own eating, but that their stuffed skins might become ornamental in the museum of her master. It is true that she was allowed to eat up the common fill as the wages of her labour, just as the warrior eats up, in another sense, the common fill of that country for whose glory he slaughters away at so valiant a rate; but before this was done it was *Le roi le veut* in the one case as in the other. Well, in the course of her scientific labours, this cat brought home a fiery-crested wren just at the season when those birds breed. The trees were sought, the nest was found, other naturalists beat other bushes whether with or without the aid of feline sagacity and claws; and the result was that the fiery-crested wren is by no means a very rare bird in the southern parts of England.

In its habits, this bird appears to differ little from the golden-crest; but it is larger in size, and not so familiar in its manners, neither has it been found in such cold places as the other. On the continent, it is much more numerous than in Britain and also much more migrant, although it does not occur in such numbers on its autumnal flight as the other. Small as the other is, for, as we have said, there are six dozen birds to the pound, it is highly relished by the ornithophagi in some parts of central Germany, and the capturing it by means of calls, which it readily obeys, is a regular trade in the season.

The top of the crest in this one is bright and glowing fire-red, with three black streaks divided by two white ones on the base at each side, whereas the golden crest has only one black streak. This is only a trifling character, but it seems to be quite constant in the species. The bill is also thicker at the base, and larger and stouter in its whole length.

It is very probable that this bird had been often seen before the singular discovery of it by the cat, but that it had been confounded with the other and much

more common one. It is also probable that the crested wren of North America is a different species, although it resembles the fiery crest more than it does the other eastern species. It is about four inches long, and six and a half in the stretch of the wings, and one half heavier than our gold crest, being about one hundred and twenty grains, while ours is eighty. The upper part is yellowish olive, with grey on the hind neck, a white line passes across the forehead and over the eyes, above this there is a line of black extending the whole length of the top of the head, above this again the yellow, and, where the yellow feathers of the two sides meet, there is a line of bright fire red, so that the bird is both golden and fiery in the crest. The two lobes which form the crest, open and shut at the pleasure of the bird, and have a very pretty effect when it is whisking about among the leaves and twigs. From the gape to the eye is dotted with black, there is a white spot under the eye, then a black line extending as far as the ear covert, and a white one below it. The breast, the flanks, and the vent feathers are cream colour; the wings dusky, with yellow margins to the quills, white tips to the greater coverts, and a black line immediately under them. The tail is long, forked, of a dusky colour with yellowish orange margins to the lateral feathers. The legs are brown, the feet and claws yellow and the bill black.

In the middle states of the American union it is a regular bird of passage, arriving from the south about the first of April, and continuing through that month and part of May, by the close of which the whole have disappeared. They return again in October in much greater numbers, and are particularly active and useful in clearing the copses and orchards from insects. At that season they are in excellent condition. They continue in the central states till the winter sets in, and then they move southward to the cedar swamps and other wooded places near the sea and the rivers of the southern states.

Their migrations in America are so regular, and their numbers so considerable, that they are a good subject in which to observe the general habit of migration, especially in its different characters upon the middle passage at the two seasons. On their spring passage, the birds are excited by the physiological impulse, and they keep moving onwards, and pass over the ground in succession, so that they do not appear so numerous at any one place as they do in the autumn, at which time their chief object is food, and where they find that in abundance they remain till it is exhausted, or till the severity of the weather shuts them out from it or otherwise obliges them to retire. Autumn is also the season of plenty; but that alone is not the reason why birds and other animals are in best condition at that time; for much also depends upon the fact that the whole energy of their nature is concentrated upon the operation of feeding.—In the middle states of America this wren never sings, its voice being only a very feeble chirp; but it is a songster, though a very subdued one, in the more northerly places in which it breeds. *Wilsonii*, or *Auriflamma*, ought perhaps to be the name of this one, to distinguish it from the crested wrens of Europe.

The Ruby-crested Wren (*R. calendula*) is another American species, very similar to the former in size and in habits, but not just exactly the same. The upper parts are nearly the same colour as in the preceding species, only more inclining to yellow, and

with no grey on the hind neck. The dark colour on the wings and tail is purplish brown instead of dusky, and the under parts are yellowish white. The coloured part of the crest is a spot of bright ruby red; which is alternately hidden and exposed by the feathers at the sides. The feet are of the same colour as in the former species, only the yellow is a little brighter. They come rather earlier in the spring into the middle states, and they are rather later in the autumn; and probably they breed farther to the north. They are exceedingly active in the trees, and clear them of vast numbers of insects, though in the spring they stand accused of eating the essential parts of the blossoms of early fruit trees. In this, however, there is probably the same mistake which is often made respecting the tits and some others of the more active and useful birds of our own country. Wilson says they "are particularly numerous in the month of October, and the beginning of November, in orchards among the decaying leaves of the apple trees that, at that season, are infested with great numbers of black-winged insects, among which they (the wrens) make great havoc. I have often regretted the painful necessity one is under of taking away the lives of such inoffensive, useful little creatures, merely to obtain a more perfect knowledge of the species; for they appear so busy, so active and unsuspecting, as to continue searching about the same twig, even after their companions have been shot down beside them. They are more remarkably so in autumn, which may be owing to the great number of young and inexperienced birds which are then among them; and frequently, at this season, I have stood under the tree motionless to observe them, while they glanced among the bare branches, sometimes within a foot or two of my head. They are extremely adroit at catching their prey; have only at times a feeble chirp; visit the tops of the tallest trees as well as the lowest bushes; and continue generally for a considerable time among the branches of the same tree, darting about from place to place; appearing, when on the top of a high maple, no bigger than humble bees."

The above quotation contains by far the best account of the autumnal action of these birds that has ever been published; and it is not confined to the ruby-crowned species, but applies equally to all the rest. Wilson is not quite correct in supposing that the fearlessness of the birds in autumn is owing to the *inexperience* of the young, for old and young are equally fearless, and equally unaffected by what we call experience. In the autumn the whole energy of the bird is, as we have said, concentrated upon its feeding; whereas in the spring it is actuated by another impulse, along with which there is awakened that vigilance which comes to its full development at the time when the birds leave their nests and young. What we are accustomed to call the results of experience in birds, are all produced by the circumstances in which they are placed at the time, some of which are local as arising from the place, and others seasonal as arising from themselves.

There is a fine instance of natural adaptation to be traced here. Autumn is the time when the bud-protecting birds are most on the alert; and have no impulse to draw their attention from their labour; and autumn is the time at which that labour is most valuable. It depends in a great measure upon the character of the weather in the spring, whether the

insect egg which is lodged in the bud shall become a wasting canker-worm or not; but if the egg is there there is never any security against the grub. Now the larvæ or grubs which destroy the buds, especially the flower-buds of fruit trees, are all produced from eggs which are deposited in the autumn; and each of the millions of insects which these little birds capture, is the means of preventing the deposition of a vast number of eggs. If, therefore, there is any one time at which the birds which range the twigs and buds claim our especial protection, that time is the autumn; for he who wantonly shoots one little bird in the orchard during that season, is almost certain to pay for his sport; not only by a bushel of next year's apples, but by serious injury to the trees.

With us, these autumnal labours are not performed so much by the crested wrens, as by the tits (see the article *TIT*); but our crested wrens are of great service to the copses and woods, especially to the pines and other trees that have their leaves on in the winter. The leaves of such trees are seldom so much eaten by insects as those of deciduous trees; but the buds of the pines especially are very subject to ravages; for the shoot of the pine is produced as wood before there is any development of the leaves or spines upon it; and until these have made some progress it is tender, sweet, juicy, and no bad vegetable for human use, to say nothing of insects. Some of the destroyers of these young shoots are flies, and some beetles; but the larvæ of both are exceedingly destructive, and would be quite ruinous were it not for such birds as the crested wrens, whose energy and light weight enable them freely to examine the minutest twig, and whose voracity fits them for consuming so many myriads of destroyers. It is true that the crested wrens are not exactly the birds which destroy the eggs and larvæ of the *Scolytidae* and other mining beetles (see the article *SCOLYTUS*), which fell whole forests and groves with the same certainty as the axe, for the bark birds, creepers, woodpeckers, and others, have the especial regulation of these; but the labours of the wrens are of most essential service in their own particular department.

It is highly probable that there are in the extensive forests of many parts of the temperate and the cold regions, or migratory between the two, other species of crested wrens besides those that we have enumerated; but as the known species differ but little in appearance, and hardly any thing in manner, the enumeration of more, even if they were known, would make little or no addition to our stock of really useful knowledge. Even in those which we have mentioned there is not much diversity of information; but we have endeavoured to point out the account of the habits among all the four; and, minute as the birds are, there are not many that offer a more pleasing study or lead the student into more delightful places.

6.—*TROGLODYTES* (WREN). The characters and manners, as well as the form of the crestless wrens, are so far like those of the crested ones, that there does not appear to be much chance of error in applying the same common name to them; but they, at the same time, differ so much that they cannot with propriety be considered as species of the same genus. In some respects the crestless wrens resemble the robins more than they do any others of the family; but they still differ considerably from them. The bill is much more slender, awl-shaped, and a little bent in

its whole length: the body is even more short and compact than that of the redbreast. The habits are nearly the same, only the wren is a more hiding bird, which has occasioned the name *Troglodytes*, or a dweller in holes. There are many birds that have been called wrens, which are not true wrens in either their characters or their habits; and so we shall confine our notice to one or two species which properly belong to the genus. They are birds of the cold and temperate parts of the northern hemisphere.

Common Wren (*T. vulgaris*). This species has been called *Europæus*, but not very properly, for it is equally abundant in the north of Asia, and also, though perhaps with some difference of appearance, (which is usual among similar birds in the two continents,) in the more northerly parts of America. In the middle states it is called the "winter" wren, to distinguish it from another species which comes from the south in spring, as this one does from the north in autumn, and is on that account called the "summer" wren. On the eastern continent it is also known most familiarly as a winter bird, but it is not so migratory as it is in America, and in Britain it, perhaps, seldom migrates farther than between the house and the nearest grove. As a household bird in the cold season, its history is closely connected with that of the redbreast, and popular story has placed the two in the relation of man and wife, "Kitty Wren" being the spouse of red-breasted "Robin." Of course, the paucity of the supposed wives did not occur to the rustics; but if their theory had been true, the robins would have deserved the epithet *Cælebs* far more than the chaffinch, for there are usually fifty robins seen for one wren, and thus the former, did they depend on the latter, would be as badly wived as the folks of Australia.

In its lineal dimensions, the common wren does not differ much from the crested ones, the length being about four inches, and the stretch of the wings about six. The body is also short, and the tail long, though, perhaps, not quite so long as in the crested ones, and it is not forked; it is in general borne sloping upward at a considerable angle with the axis of the body. The weight is, however, fully three times that of the gold-crest, being about two hundred and fifty grains to eighty. It is, indeed, one of the heaviest, and also the stoutest, for its inches, of all the feathered race.

Of course, the bird is fitted for very different action from that of the light and airy crested wrens; for while they are beating about for their food among the buds and sprays, it is generally ranging among, or below, the underwood. It lodges in holes of the earth, of walls, of trees, or in heaps of stones, or under fallen timber; and even during the day it may be seen to leap about by the assistance of its wings rather than to fly. Like the robins, the wrens never formally associate with each other; for in the places where they are most abundant, each individual seems to act entirely for itself. In cold weather, however, several of them may sometimes be found in the same hole; but there is no likelihood of their entering these by mutual consent, and their courage may be so taken down by the cold, that their pugnacity, which is pretty strong and forward at other times, may make them prefer heat to hostility.

The wren is a dusky-looking little bird, and when it moves about in a pile of sticks, or under the leafless brushwood, it might, at first sight, be mistaken

for a mouse. Its bill is about half an inch long, a little bent, of a dull brownish colour, and so slender that it can with difficulty be seen even at a little distance, if not projected against something much lighter in the colour; the irides are hazel, and the eyes, though not large, are full and expressive; the whole of the upper part is reddish brown, clouded with obscure cross bars of dusky, and the under parts are of the same brown, but lighter in the shade; the quills and tail-feathers are dusky brown, and there are very few markings on any part, except an obscure pale streak over the eye, and a few white spots on the under coverts of the tail; the feet are of the same brown as the general tint of the body; and perhaps there are few instances of a more perfect adaptation of the colour of birds of the same family to the places which they inhabit than the fine but delicate tints of the crested wrens on the top of the tree, and the sober livery of this one, which breeds with the mice among the brushwood at the bottom. Insects and earthworms, especially the latter, form at least the principal food of the common wren; and, small as its bill is, we have seen it in a garden pull from the ground an earthworm as long as itself, and nearly as thick as a goose-quill, and fly to the foot of an apple-tree, and, by the process of swallowing alone, bolt it in a very short time. It has been said, though we suspect with no great truth, that the robin cleans its worms. We never saw one so nice in its eating, and certainly the wren takes them as they are.

As a winter bird, the wren has none of the peculiar fascinations of the robin. It comes near to the house, but not in; and it does not appear to be so thankful for crumbs of bread as robin. Altogether it is a much more obscure bird than the other, and seldom appears in open places, or perched at any great elevation on trees. It neither comes so early nor so regularly as the other, and it departs sooner in the spring. The warm and shaded places about which it lurks appear to have a better supply of food during a greater part of the year than the haunts of the robin. It does not do a great deal of garden work on the trees themselves, as the other does; but we must not, for this reason, suppose that it is wholly without its use. Notwithstanding its partiality for hiding-places, there appears to be a good deal of curiosity about this wren; and, indeed, it seems to be a pretty general law among animals, that those which find their food by prying about in obscure or confined places, are very apt to examine everything new with a great deal of attention. Many other birds, which you surprise by walking into the garden or the shrubbery, betake themselves to their perches or hiding-places the instant that they observe you; but not so the wren, for it leaps out of the bush to reconnoitre you; and if you stand perfectly still, it will remain "at gaze" for several minutes; but if you follow it, it moves to two or three places, still eyeing you with a sort of wondering curiosity, till at last it leaps away you know not where. If you keep your first position steadily for some time, the chance is, that it will treat you in a different manner, for it will leap to some perch, not a very elevated one, and salute you with its song, which, though far from a varied or powerful one, is much more shrill and sweet than you would be prepared to expect from a creature so mouse-like in its colour and habits. Cats lie much in wait for wrens where they are abundant, but they do not appear to be so successful in catching them as in

catching many other birds; for the cat is found with many robins for one wren even in places distant from towns and near woods, where the two birds are about equally numerous. This is another proof of the very keen eye of this little bird; and we have again and again seen grinnalkin get within her distance, and take her spring, but the wren bounded a little aside, and, leaping on a twig, looked down upon her with perfect unconcern. The fact is, that birds of moderate range in the free air are much more frequently destroyed by cats than birds of holes and corners, as they do not appear to have their eyes so much about them, and are more awake to sounds than to sights. It is chiefly in the very severe weather that wrens come to the close vicinity of houses, and at these times they sing, although every other bird is mute, save the querulous and complaining chirp, which has no expression of pleasure to the bird, or pleasurable to the hearer. In the northern parts of the country, when the snow lies confirmed for many weeks to the depth of several feet over the common pasture of the wren, and the bird must resort to the vicinity of the farm-house, or the bank of the yet unfrozen fountain or stream, it is delightful to see how the little thing joys in the warmth of the sun, leaps upon some projecting point, and pours forth its little song as jocularly as any lark that ever proclaimed the spring from the top of the morning sky.

The nest of the wren is always in a warm and sheltered place, though differently sheltered according to the nature of the ground. Where there are young pines, with branches near the ground, and heath under these, the place is especially favourite, as the pine shuts out the rain almost as completely as a roof. Whether it is the general habit of the bird, we will not pretend to say, because we have intimately studied its economy only in places of a peculiar character; but we never met with a wren's nest under a young pine except on the north or the north-east side. We have not certainly had any personal means of verifying the fact, that the nest is begun at the top and built downwards, neither did we ever see one placed at any considerable height above the ground, though they were all, in a way, a sort of dome nests, with a lateral opening, and so concealed in the underwood as not to be readily found. We have usually found a few small sticks, but these formed only the timbers of the fabric, the substantial part of the external nest being moss or lichen, according as the one or the other was most readily found. The interior was copiously lined with feathers, and never with wool, which indeed it could not be, as there were then no sheep in that part of the country. In districts of a different description, the nest, of course, varies both in situation and materials; for birds, like men, must be contented with such places and materials as they can command; and it is well for both that their Almighty Creator has endowed them with this flexibility to circumstances. Wrens are prolific birds. We never saw more than from six to eight eggs in a nest; but the authorities say that they are sometimes as many as eighteen, and even more, and we see no reason for doubting the authorities—though it were very desirable that no such thing as an authority in natural history existed. The eggs are very small, of a white colour, with the faintest possible pinky tinge over the greater part of their surface, and a neatly mottled band of rust-coloured dots near the larger end.

From Wilson's account, and we can have none more accurate, it should seem that the winter wren of America is a smaller bird than the common wren of Europe, though the colours, and all the other particulars, are so nearly the same as to leave but little doubt as to the identity of the species. It is, however, much more of a migrant, and does not breed in the central states; but that is nothing, as all birds are more migrant in America than Europe. The account of its winter habits, which we shall give in Wilson's own words, would answer equally well for our wren. "During his residence here, he frequents the projecting banks of creeks, old roads, decayed logs, small bushes, and rushes near watery places; he even approaches the farm house, rambles about the wood hill, creeping among the interstices like a mouse. With tail erect, which is his constant habit, mounted on some projecting point or pinnacle, he sings with great animation. Even in the yards, gardens, and outhouses of the city, he appears familiar and quite at home." According to the same authority, the dimensions are smaller than those of the European wren, but the colours are exactly the same.

House Wren, or summer Wren (T. ædon). This is the American species which alternates with the former, coming when it returns in the spring, and retiring when it comes in the autumn. It arrives in Pennsylvania in April, and rarely tarries so late as October. It is larger than the winter wren, and different in colour. The length is four inches and a half, and the extent of the wings five and three quarters. The upper part is deep brown, clearer in the tint than that on the other species; but clouded in the same way with transverse markings of dusky black, except upon the head and neck. The cheeks, throat and breast, and also the legs and feet, are clay colour; the under part is spotted with black, brown and white, though these colours do not appear unless the feathers are ruffled. The bill is slightly bent and black, having some resemblance to the bills of the creepers. Both sexes are nearly alike in their plumage.

In Pennsylvania, and the other central states of America, this is a very familiar bird, and one which finds favour in the eyes of the people, from the vast number of insects which it destroys. It builds in hollow trees, or under the projecting eaves of houses, but the people often erect boxes on the tops of poles for its accommodation. These are in or near the garden, in order that the birds may more successfully carry on the war against the caterpillars. "If," says the grand historian of the birds of the United States, "all these conveniences are wanting, he will even put up with an old hat nailed to the weather boards, with a small hole for entrance; and, if even this be denied him, he will find some hole, corner, or crevice about the house, barn, or stable, rather than abandon the dwellings of man. In the month of June, a man hung his coat under a shed, near the barn; two or three days elapsed before he had occasion to put it on again; thrusting his arm up the sleeve, he found it completely filled with rubbish, as he expressed it, and on extricating the whole mass, found it to be the nest of a wren completely finished, and lined with a large quantity of feathers. In his retreat, he was followed by the little forlorn proprietors, who scolded him with great vehemence, for thus ruining the whole economy of their domestic affairs. The twigs with which the outward parts of the nest are constructed are stout and crooked, that they may better hook into

one another, and the hole or entrance is so much shut up to prevent the intrusion of snakes or cats, that it appears almost impossible that the body of the bird could be admitted. Within this, is a layer of fine dead stalks of grass, and lastly feathers."

An anecdote of Wilson's with regard to this species is so interesting and so well told, that we cannot resist the temptation of quoting it. "This little bird has a strong antipathy to cats; for, having frequent occasion to glean among the currant bushes, and other shrubbery in the gardens, these lurking enemies of the feathered race often prove fatal to him. A box fixed upon the window of the room where I slept, was taken possession of by a pair of wrens. Already the nest was built, and two eggs laid, when one day, the window being open, as well as the room door, the female wren, venturing too far into the room to reconnoitre, was sprung upon by Grimaldin, who had planted herself there for the purpose; and, before relief could be given, was destroyed. Curious to see how the survivor would demean himself, I watched him carefully for several days. At first he sung with great vivacity for an hour or so, but, becoming uneasy, went off for half an hour; on his return, he chanted again as before, went to the top of the house, stable, and weeping willow, that she might hear him; but seeing no appearance of her, he returned once more, visited the nest, ventured cautiously into the window, gazed about with suspicious looks, his voice sinking to a low melancholy note, as he stretched his little neck about in every direction. Returning to the box, he seemed for some minutes at a loss what to do, and soon after went off, as I thought, altogether, for I saw no more of him that day. Towards the afternoon of the second day, he again made his appearance, accompanied by a new female, who seemed exceedingly timorous and shy, and who, after great hesitation, entered the box; at this moment the little widower or bridegroom seemed as if he would warble out his very life with ecstasy of joy. After remaining about half a minute in, they both flew off; but returned in a few minutes, and instantly began to carry out the eggs, feathers, and some of the sticks, supplying the place of the two latter with materials of the same sort; and ultimately succeeded in raising a brood of seven young, all of which escaped in safety."

The above, of the perfect truth of which there cannot be the least question, is one of the most curious in the whole history of animals of whatever class they may be; and if one was to build a theory of the reasoning powers of animals, perhaps there is no better foundation on which it could be erected; but we have neither room nor inclination for such theories; and therefore, we shall leave the reader to draw from the account, of the correctness of which there can be no doubt, whatever conclusion may be the most agreeable to himself; meanwhile we proceed with our notice of the bird, as with that of all other irrational animals.

We cannot resist quoting a little more of the account of this highly interesting bird, in the description of which Wilson is peculiarly happy. "The immense number of insects which this sociable little bird removes from the garden and fruit trees ought to endear him to every cultivator, even if he had nothing else to recommend him; but his notes, loud, sprightly, tremulous, and repeated every few seconds with great animation, are extremely agreeable. In the heat of summer, families often dine under the piazza, adjoining green canopies of mantling grape-vines, gourds,

&c., while over-head the trilling vivacity of the wren, mingled with the warbling mimicry of the cat-bird, and the distant softened sounds of other songsters, form a soul-soothing and almost heavenly music, breathing peace, innocence, and rural repose. The European who judges of the song of this species by that of his own wren will do injustice to the former, as in strength of tone and execution it is far superior, as well as the bird is in size, figure, and elegance of markings, to the European one. Its manners are also different; its sociability greater. It is no underground inhabitant; its nest is differently constructed, the number of its eggs fewer; it is also migratory, and has the tail and bill much longer. Its food is insects and caterpillars; and, while supplying the wants of its young, it destroys, on a moderate calculation, many hundreds a day, and greatly circumscribes the ravages of these vermin. It is a bold and insolent bird against those of the titmouse or woodpecker kind that venture to build within its jurisdiction, attacking them without hesitation, though twice its size, and generally forcing them to decamp. Even the blue-bird, who claims an equal and a sort of hereditary right to the box in the garden, when attacked by this little impertinent, soon relinquishes the contest, the mild placidness of his disposition not being a match for the fiery impetuosity of his little antagonist. With those of his own species who settle and build near him, he has frequent squabbles; and when the respective females are sitting, each strains his whole powers of song to excel the other. When the young are hatched, the hurry and press of business leave no time for disputing, so true it is that idleness is the mother of mischief. These birds are not confined to the country; they are to be heard on the tops of houses in the most central parts of our cities, singing with great energy. Scarce a house or cottage in the country is without a pair of them, and sometimes two."

Many other birds than those which have been enumerated in this sketch are called wrens, some of which are warblers, some creepers, and some belong to other genera. It is very natural, and perhaps unavoidable, to have this general application of the name of a bird with which every one is familiar, to other birds that are less known, but which resemble the well-known one more or less in appearance, in habits, or in both. From its familiarity in the winter, as well as from the peculiarity of its appearance and its manners, every body, whose ornithological knowledge extends beyond the house-sparrow and the goose, knows the common wren, and thus it becomes a very good key to the mere distinguishing of those birds which are called after it. But when we come to more accurate knowledge, which depends upon the whole structure and habits of the birds, those popular extensions of the same name are by no means so convenient.

There still remains a small section of sylvan birds, belonging obviously to the family now under notice, which some have classed with the wrens, and some with the warblers properly so called (*Curruca*). But they do not properly belong to either. In the English descriptions they have pretty generally been denominated "willow wrens," or "willow warblers;" and therefore, without pretending that it is accurate, we shall call them by the general name of

8. SALICARIA—Willow birds. It must not be supposed that these birds are never to be found but

among willows, any more than that willows are never to be found without these birds; for such rigidity of expression as this could not be applied in any department of natural history. All that is meant is that, in the places which these birds visit in their migrations, especially their summer one, they chiefly resort to situations which are peculiarly favourable to the growth of willows, whether there happen to be willows upon them or not. They have been called marsh-warblers; but that name is not altogether accurate, as they do not resort to the marshes properly so called, but to those places of the banks of pools and streams which have a cover of very tall and close vegetation in the summer, whether that vegetation consists of willows, reeds, sedges, tall aquatic grasses, or any other plants, provided those plants grow tall enough for affording the requisite shelter, and there is damp enough for affording the peculiar supply of food which these birds require. Their characters, as a distinct genus or subgenus, are not very strikingly marked, but still there is a likeness among all the known species, and a dissimilarity to all the other genera or subgenera of the family. They have the body more slender and tapering at the shoulders than the other warblers; the upper part of the head is flattened; the wings are short and rounded; and the tail is long and wedge-shaped at the end. Their whole form and expression clearly indicate to any one who has been in the habit of paying even a very slight attention to the haunts and the forms of birds as adapted to each other, that these are formed for boring their way among very close obstacles, getting on the wing in very confined places, and rising and falling in their flight with much more facility than they make forward progress on the wing. While they are in England they roam very little, and are rarely seen upon the wing, except hovering over the osier holt, or the bed of reeds or sedges, or taking very short flights from one part of it to another. As the foreign birds, which should be included in this subgenus, are not well defined, we shall confine this notice to those which are met with in Britain. They are birds of which it is not easy to study so as properly to understand their manners; for their haunts are neither easy nor pleasant even in our latitudes, and in warm climates they are highly dangerous both on account of the miasmata they give out and the reptiles and other awkward inhabitants which they contain. They are not all equally birds of the rank aquatic vegetation; and some of them have little or no claim to be called warblers, for their voices are any thing but musical. There are three known species of them, all of which are regular summer visitants, not rare by the streams and pools in the south of England, diminishing in numbers as we proceed northward, and there is no well-authenticated account of their appearance in Scotland.

The Sedge Warbler (S. phragmitis). This is the sedge wren of popular language, but it is unlike any of the wrens properly so called, both in appearance and in manners. It is about the same weight as the common wren, but it is more than an inch longer, and of a far more slender and delicate shape. It is about five inches and a half in length, seven inches in the stretch of the wings; the head is narrow as well as depressed on the crown, and the bill pointed, of a dusky colour on the upper part, and white on the under; the colours are sober, according well with the retiring habit of the bird; the upper parts are

soft yellowish-brown, pure on the middle part from the back of the head to the upper tail-coverts, but slightly marked with rust colour on the scapular-feathers and the coverts of the wings; the quills and tail-feathers are of the same colour as the rest of the upper part, but little deeper in the tint, and each feather obscurely margined with dusky; the ground colour of the cheeks, and a small portion of the sides of the upper neck, are dark brown; the chin and throat are yellowish-white, deepening into a sort of brownish-yellow on the breast, and gradually fading to the same tint as the throat upon the belly: all these colours are so subdued, and fade so gradually into each other, that the birds cannot well be described by them; there is one marking, however, by which it may at once be distinguished from all the other little birds that are found in the same places; from the gape, or rather from the base of the upper mandible, a white streak extends in the direction of the eye, but before it reaches that organ it divides into two, so that that organ is enclosed in the fork; this marking being upon a dark brown ground is very conspicuous, and it is constant in the species, so that it is a ready means of distinction.

This bird arrives in England about the middle of April, but as it comes silently to take possession of its breeding grounds, it is but little noticed. When the song begins, it is rather a feeble one, but not without music. It is heard to most effect in the early morning, and again toward evening; but it also sings occasionally from its cover during the day. It sings in concealment from the visible perch, which, however, is never very high, and also in its short flights. The place of the nest varies with the locality, being within a bush among the stems of reeds, or upon a dry stool in a willow holt, according to circumstances. Vegetable fibres and moss are the chief materials, and the lining of the nest is finer fibres, with occasionally an admixture of a few hairs. The eggs are five or six in number, of a pale brownish colour mottled with darker. The food consists of winged insects captured among the rank vegetation; and probably also of larvæ, small mollusca, and worms; indeed, all the little birds which are animal feeders are pretty miscellaneous, and do not refuse any kind of small life that may come in their way. From the accounts, it would seem that this species is more generally distributed over the country than the one about to be mentioned; but there is a degree of uncertainty about all these little birds of the tall vegetation by the waters, as one bird is apt to be heard and another seen. The reed-warbler, or even the reed-sparrow, may be the bird of which a glance is barely got before it glides into its cover; and then if the observer throws a stone in order to get another peep at his bird, that is sure to set the sedge-warbler a singing if it happen to be in the cover.

The *Reed-Warbler* (*S. arundinacea*), is nearly the same in size as the last-mentioned species, and not very different in colour. Still, however, the two can be discriminated without much difficulty. The bill of this one is yellowish on the under side, broader at the base than that of the former species, and there are two or three stiff hairs at the angle of the gape, which would lead one to conclude that it feeds more exclusively upon insects in the winged or perfect state, though the mode in which it captures them has not been well ascertained. The plumage of the whole upper part is plain ash-brown, with the quills and

tail-feathers edged with the same, but dusky brown in the greater part of the breadth; the under parts are yellowish-white, paler on the middle, and passing through a slight brownish tinge on the flanks into the olive on the back; the streak from the gape to the eye is very obscure, and there is no brown on the cheek to set off either it or the little pale-coloured cloud on the eyebrow. This is a soft bird in its colouring, but one of the least gay that are to be met with.

It comes about the same time as the sedge warbler, but it does not come in such numbers, nor is it so widely distributed over the country. It is chiefly found near the coasts, and on the lower estuaries of the great rivers, rather than on the banks of the more upland streams, however rank they may be with vegetation. It is more aquatic than the sedge bird; and though they are often found in the near vicinity of each other, they are not found upon precisely the same spots. The sedge and the reed, after which they have been called, point out tolerably well the difference of location in the birds. The sedge and the reed are very close neighbours; but the sedge is only close by the water, while the reed is in it. The two birds have a similar distinction in their habitats. There is generally, if not always, an earthy surface under where the sedge-warbler has its nest, and that nest is in general placed upon a solid support; but the reed-warbler in general nestles over the water, though only where that water is thickly covered with reeds. Whether those reeds are upon a flat shallow of the river or on a pool, they are resorted to; and hence the bird is often found on neglected mill-ponds, and other small patches of water. Where there are extensive brick-works, the makers often keep reed-pools upon some of the places from which the brick earth has been taken, as these reeds are valuable to them as covering for the bricks in the course of the manufacture. There are several such reed-pools in the neighbourhood of London, and wherever they are they are sure to be frequented by reed-warblers in the summer. When the reeds are so close as that several of them can be employed to support the nest, it is usually placed upon them, composed first of coarser and then of finer vegetable matters, but never with hair or feathers, as the bird does not frequent places where these are likely to be obtained. The eggs are a little larger than those of the sedge-warbler, of a greenish white colour in the ground, and marked with dusky brown. So far as has been observed, the nest is never placed on the ground, though it is sometimes among the lower branches of a thick tree or bush near the water, or occasionally, but rarely, in a tuft of tall and shady herbaceous vegetation.

It is understood to come rather later and depart earlier than the sedge warbler; but this is not clearly ascertained, as it is silent when it first comes, and also before it departs. This bird has much more powerful action of the feet than the former species, and, when necessary, it can cling very dexterously to the stem of a reed, though it usually perches upon the leaves, or upon stems which are in a sloping position. Its song is sweet, but so subdued that it seems as if it were whispered, and it is heard only at very short distances.

The *Grasshopper Warbler* (*S. locustella*) has been sometimes described as a third species of these aquatic birds; but though it is often in situations near the

water, it is properly a land bird, or rather a bush bird on rich places. It is about the same length as the two species which have been mentioned; but it is more stoutly made, and rather heavier. The colours are also a little more distinctly marked. The general tint of the upper part is brownish olive, with the middle of each feather on the back darker, producing a pretty effect. The streak over the eye, the chin, the throat, and the belly, are yellowish white; the breast, flanks, and tibiae, brownish; the two last obscurely streaked with darker. The quills and tail-feathers are dusky, with their external webs olive. The tail is much wedge-shaped, the lateral feathers being an inch shorter than the middle ones; and each individual feather is rounded or pointed at the tip. The wings are very short and much rounded. The legs are brown, and the claws horn colour; that on the hind toe being short and crooked, quite unlike the hind claw of the lark, though the bird has sometimes been called a lark.

It is a summer visitant, resorting to brakes, building its nest in close cover, and altogether living in much concealment. The nest is but a rude structure, and composed wholly of vegetable matter; the eggs are four or five in number, of a bluish white colour, and without any spots. The only note which it has been ascertained to utter, is the hissing one, something like the sound of the grasshopper; and it is highly probable that the one voice may in some instances have been taken for the other. The place of the utterer of these hissing sounds is not very easily ascertained, as they strike the ear like echoes, and one is apt to suppose that they come from the very opposite direction. This is a tender as well as a hiding bird, and is not found in upland places; indeed, it is rare as well as local.

For the remaining genus of the family *Motacilla*, which Linnæus made the generic name of all the species, we must refer the reader to the article *WAG-TAIL*.

SYMPHORIA (Pursh). A genus of hardy deciduous shrubs from North America, belonging to *Caprifoliaceæ*. Linnæus considered this a *Lonicera* (honeysuckle), but it was subsequently made a separate genus by Pursh.

SYMPHYTUM (Linnæus). A genus of European herbs, having shewy pentandrous flowers, and belonging to *Boraginææ*. Two of the species are natives of England, where they are called comfrey. One of the Caucasian species, the *S. asperrimum* of the Hortus Kewensis, has been lately recommended to British farmers as a green forage plant, and has been cultivated on a small scale in various places with considerable success.

SYMPLOCARPUS (Nuttal). A North American aquatic, belonging to the *Aroideæ*. The plant was formerly called *Dracontium* by Linnæus, and *Polthos* by the author of the Botanical Magazine. It is in our collections planted in a marshy situation, and is increased by division.

SYMPLOCINEÆ. A natural order containing only one genus, viz., *Symplocos*, which gives the title, and is the type. Of this there are four species bearing polyadelphous flowers, and are shrubs with serrated leaves, turning yellow in drying. The flowers are small, white, and rather fragrant. The *S. tinctoria* is used as a yellow dye, under the name of sweet-leaf in America.

SYNALLAXIS (no proper English name). A

genus of rather handsome little birds, belonging to Cuvier's tenuirostral family of *Passeræ*, and bearing no inconsiderable resemblance to the nuthatches of Europe. They are all tree birds, and are known to Europe and naturalists chiefly as Brazilian; but it is probable that they occur in the rich woods of other parts of tropical America. The characters are: the bill not very long, slender, pointed, very much compressed, naked at the base, the mandibles slightly curved inwards at their margins; the upper one a little curved at the tip, the under one straight. The nostrils broad and lateral oblong, covered in part with a small vaulted membrane and ornamented with feathers. The feet of mean length, with three toes to the front and one to the rear; the two lateral front toes of equal length, and united at their bases to the middle one, which is of the same length as the hind toe. The wings are very short and rounded; the first quill very short, the second and third gradually longer, and the fourth the longest in the wing. The tail very long and wedge-shaped, the feathers of it broad in great part of their length, but tapering to points. They correspond in America to certain little birds, which are found in the tropical forests of other parts of the world, but not enough is known of them for the establishing of a proper classification.

S. albescent has the upper part olive ash; the top of the head and the hind neck bright red; the front eye-brows and cheeks olive grey; the lesser wing coverts russet; and the tail feathers olive. The chin and belly white; the throat clouded with black; and the breast and flanks reddish grey. The bill black, with the exception of the middle of the lower mandible which is white. The length about five inches and three quarters.

S. rutilans, has the upper part of the body olive grey, clouded with deep grey; the forehead, brows, cheeks, sides of the neck, breast, and wing-coverts, bright red. The tail-feathers blackish, with glosses of chestnut red; the quills, and also a spot on the throat, black; the rest of the under part greenish grey, clouded with deep red; the bill greyish in the chief part of its length; but black at the tip; the feet black; the length about six inches.

S. tessellata. The top of the head bright red; the back mottled with regular darkish spots; the coverts of the wings brown, with spots of a different shade; the tail feathers brown and much wedge-shaped; the region of the eye whitish, finely mottled with minute brown spots; the cheeks bluish or greenish white, with small mustachios of black; the chin yellow; a large spot of black on the throat; the breast, fore part of the belly, and flanks, bright fawn-colour; the rest of the under part whitish; the bill grey at the base, black at the tip; the feet brown; the length seven inches.

S. setaria. Upper parts bright maroon red; forehead ash grey; top of the head clear grey; nape and upper part of the neck, brown, finely streaked with white; a patch of white on the bastard wing; quills blackish brown, bordered with maroon red; tail-feathers the same, much wedge-shaped, and with brighter borders; chin, throat, and breast, greyish white, dotted with black, and the rest of the under parts clear fawn; bill ash-colour, and white at the base; feet black; length seven inches.

S. cinerescens. Olive; brown above; the quills brown, bordered with maroon; the tail-feathers russet, the chin white, finely lined with lilac; a large black

spot on the breast; the cheeks, and also all the under parts, slate grey; the bill ash; the feet brown, the length six inches.

S. Ruficauda. The upper part brown, slightly clouded with red; the quills and tail feathers red; the chin yellow; the throat, breast, and belly, white; the under parts, backwards, grey; the bill and feet black; the length five inches.

S. Ruficapillus. Upper part brown; top of the head red; eye streak yellow; forehead and cheeks greyish ash; quills brown, margined with red; tail much wedged, and of a clear maroon colour; breast grey; flanks olive; belly whitish; bill black; feet brown; length five inches.

Little is known of them save the colours and sizes. They appear to stand in nearly the same relations to the tropical forests as the warblers do to the temperate ones, and we have mentioned them chiefly for the contrast of the plumage.

SYNDACTYLI, a family of birds which have the outer and middle toes of nearly the same length, and soldered together. They consist of bee-eaters, king-fishers, hornbills, and a few other genera. See BIRD.

SYNGNATHUS (Pipe-fish), or perhaps SYNGNATHIDÆ, the pipe-fish family, singularly formed fishes, belonging to the order *Lophobranchii*, or those that have the gills in tufts. The name *Syngnathus* means that the jaws are united, and the fishes have the mouth drawn out into a sort of tube or pipe. The characters are: the mouth drawn out into a sort of tube, formed of prolongations of the *ethmoïde*, the vomer, the tympanal, the preopercular, and the subopercular bones, and not of the genus properly so called; and this lengthened tube, which gives a very singular form to the head of the fish, has a mouth of the ordinary structure at its termination; but the opening of it is nearly vertical. The breathing aperture is at the nape. In their fins they vary much, the greater portion have no ventrals, some want only the ventrals, others have no fins but the dorsal and caudal, and others again have only the dorsal. Their bodies are in general very slender and much elongated, some of them have a considerable similarity to snakes, and others to worms; and some are popularly called sea-needles. Some of them have the tails prehensile, or capable of laying hold of sea-weed or other substances by curling the tail round them, and we believe it can curl round with equal readiness in every direction. In an economical point of view they are of no value; but they have an interest with the mere lovers of nature, in being among the most singular looking of all the productions of the sea, while the very singular mode of their production which differs not only from that of all other fishes, but of every known animal, gives them a still higher degree of interest in the estimation of physiologists.

Essentially they are fishes even in this the most peculiar part of their economy,—that is to say, they are females and males, the first of which prepares roe and the second milt, just as in other fishes. Here, however, the parallel ends, and we come to the singular peculiarity. The females are oviparous, bringing their eggs or roe to maturity, and then discharging them as is done by all the oviparous fishes. But the eggs so discharged by the female are not committed to the sea, they are handed over to the male in order to be hatched. The male has an abdominal or subcaudal pouch for receiving the eggs, and they not

only remain in this pouch till the young are formed and escape from the capsules of the eggs, but the said young afterwards take shelter in the pouch of the male, as a place of security from danger. The pouch is differently formed and situated in the different species, but that is a matter of detail for the particular notices of them, and the general principle is common to them all.

They thus have some resemblance to the marsupial mammalia of Australia; only, in the case of the fishes, the marsupium is on the male, while in the marsupial mammalia it is on the female. In what may be considered as the most typical members of the family, if in so singular a family any one can be considered as typical, the pouch is composed of two longitudinal lobes or leaves, which shut against each other on the lower part of the fish, and when it has this form it is chiefly if not always subcaudal; but it is sometimes made up of a number of sections, and these are generally in advance of the vent. By what kind of progress the eggs are transferred from the female to the pouch of the male, we have no means of ascertaining; and indeed we are nearly in the same ignorance as to the mode in which the females of the marsupial mammalia transfer their young to the abdominal pouch upon themselves.

The family consists of three genera, *Syngnathus*, properly so called, *Hippocampus*, and *Solenostomus*. Various species of the first of these genera are found in the British seas, chiefly but not exclusively on the south coast; and there is at least one British species of the second; but the third genus is, we believe, wholly confined to the Indian and other warm seas.

SYNGNATHUS, properly so called,—pipe-fish. There are two sections of this genus distinguished from each other by the number of the fins, and also by the form of the hatching appendage on the under side of the male. Mr. Yarrell, to whom the students of British fishes, whether scientific or amateur, are under so many obligations, has established as British two species of the one section, and three of the other. In doing this he has blended his own most accurate, valuable, and discriminating observations and dissections, with those of other competent naturalists.

1. Pipe fishes with many fins. The characters of this section, some of which, however, it possesses in common with the other one, are as follows: Body very long and slender, covered with a series of hard plates, arranged longitudinally in parallel lines. The head long, with both jaws produced in the manner that has been already stated, and united so as to form a tube, at the end of which the mouth is placed. There are pectoral, dorsal, anal, and caudal fins, but no ventrals. The fins are small, the tail very long and tapering, so as to be slender at the base of the caudal, which is shaped like a little fan. The males have a long pouch on the under part behind the vent, which is closed by two folding leaves or lobes running in a longitudinal manner, and in this pouch the eggs are hatched after they have been discharged by the female.

The use of the singular tubular extension of the mouth in these fishes has not been ascertained, neither is it understood why they have the gills so very differently formed from those of all other fishes. These gills consist of a number of little tufts, and they are defended externally by a large and firm operculum or gill cover, which does not open like that of ordinary fishes, but merely by a hole at the posterior part of

its upper edge. There seems thus to be in their breathing apparatus something between the character of the free gills of bony fishes, and the fixed gills of the *chondropterygii*. Even in the covering of their bodies, there is this intermediate sort of character. Most of the *chondropterygii* have the body covered with bony plates, or granulated with very hard tubercles; and the pipe fishes have their long and slender bodies defended by a great number of hard plates, which are variously figured or sculptured upon the surface. All the species, whether of this section or the other, and indeed all the *Lophobranchii*, or fishes with tufted gills, are inhabitants of the salt water only; and, though many of them have great swimming powers, they are seldom found at any very great distance from the land. In general, whether nearer the land or farther in the offing, they are found near sea-sand bottoms; and hence we may perhaps conclude that they feed upon the small crustacea and mollusca that have their residence in or near such sand, and on the very young fry of such fishes as deposit their eggs in the sand as a place of safety.

Some of the species, those of the present section especially, appear to follow the habit of many fishes, in approaching nearer the shores at some seasons and receding farther from them at others. When fishes do this it is usually connected with their spawning,—the seaward course is taken in order to recruit the strength and improve the growth of the individual fish; and the shallow water where they can have the influence of the direct light and heat of the sun, and also the radiation and reflection from the bottom, is undertaken in order to mature the spawn; while those which deposit their spawn, and they are by far the most numerous of fishes, find near the shore the proper places for it. In the depths of the sea there is of course little stimulus to anything at the bottom; and thus, if the spawn of fishes were placed there, it might lie inert for years or for ages. The *Syngnathii* carry their spawn about with them till it is hatched, and thus they can always have it in that temperature which is the very best for bringing it to maturity. On the British shores some, at least, of the pipe-fishes are said to go twice in the year to the deep water, but whether they spawn twice in the year has not been fully ascertained.

The *Great Pipe-fish* (*S. acus*), is perhaps the most frequently found on the British coasts, sometimes among the sea-weed just by the low-water line, and at other times in the water at considerable depths. They are seldom more than a foot and a half in length, and they come so far to maturity as to be capable of breeding when they are less than half a foot in length. These circumstances render it rather a difficult matter to say what is the proper size of them; and, indeed, the power of growth in most fishes is so indefinite, that any positive statement of their size is calculated only to mislead. All that can be said with certainty about this one is, that, though it is called the great pipe-fish, it is always a small fish as compared with the greater number of the other fishes. The male and female are very readily distinguished from each other by the presence of the abdominal valves or pouch on the former and its absence in the latter; there is generally also roe in the female, in some state of forwardness, the more so the nearer the shore we believe, and the male sometimes has roe in the abdominal pouch and sometimes not. It does not appear that the whole which are

deposited in that receptacle are brought forward at the same time; for, when the fishes have been examined, it has been found that the young in some of the ova were only beginning to be formed, while in others they were complete, and that some of the empty pellicles of the ova remained adhering to the valves of the pouch. When and how the eggs are transferred to the pouch of the male, and whether gradually or the whole production of the female at once, we are not informed, neither are we acquainted with the economy of the two after the transfer. If we were to reason from the analogy of other fishes, which however is not a conclusive mode of reasoning, notwithstanding that the milt and roe are primarily formed in the pipe fishes, just in the same manner as in the others,—if we were to reason thus, we should be inclined to say that the males must remain near the shores in order to hatch the eggs in the pouch, for some time after the females have retired to the deep water, for the purpose of recruiting their strength and preparing a new succession of eggs; this is what the general law of nature would lead us to conclude, and it is to be wished that the habits of the fish had been observed with reference to this law. As the eggs are transferred from the one to the other, we might expect that the two sexes should alternate with each other in their stay upon the coast,—that they should do this in the single pair and in the average of the whole for the season, although during that season we may expect both to be coming and going for a very considerable period of time. It is perhaps this which occasions the double resort to the deep water which is mentioned by the authorities, and which probably consists chiefly of the females at the one time, and of the males at the other. It is only of late, however, that the attention of physiological naturalists has been drawn to the subject, and therefore many observations have yet to be made before the details of their singular economy are clearly established. The statement of the leading facts in "Yarrell's British Fishes," cannot fail in being highly useful as lights to guide them who are upon the ground, and have the inclination as well as the opportunity for clearing up this and many other points in the economy of the characteristic natives of that sea which is so especially interesting to every Briton. The following account of the late Mr. Walcott's observations, as quoted by Mr. Yarrell, is very satisfactory as far as it goes, and it may also enable us to state the principal points upon which farther information is necessary, in order to complete the history of the fish in a satisfactory manner. "The male differs from the female in the belly from the vent to the tail fin being much broader, and in having for about two-thirds of its length two soft flaps, which fold together, and form a false belly or pouch. They breed in the summer; the females casting their roe into the false belly of the male. This I have asserted from having examined many, and having constantly found, early in the summer, roe in those without a false belly, but never in those with; and on opening them later in the summer, there has been no roe in those which I have termed the female, but only in the false belly of the male." Following up the train of these observations, Mr. Yarrell found, about the hottest time of the year, eggs in a state of maturity, eggs from which the young had escaped, and hollow impressions from which the capsules or cases of the eggs had parted. The different depths of water in

which both are found, before and after the transfer of the eggs, if any such difference there be, the manner in which the eggs are transferred and fecundated, and the time that they remain in the pouch before the young are fully developed, are the most essential parts which remain to be ascertained by future observations.

Risso, in his valuable work on the fishes of the Mediterranean—a sea in which those fishes are more abundant than they are upon our shores, mentions that the adult pipe-fishes show an affection for their young which is very rare among the finny tribes, they being in general just as apt to eat the fry of their own species as that of any other. But even this point has not been ascertained with that precision which is desirable in fishes of a character so very peculiar. We can understand why the male should be attached to the young of those fishes, and they to him, but then we can see no more reason for a reciprocal attachment between the female and the young, than there is in the cases of fish that spawn in the usual manner. The moment that the roe is transferred to the male all connexion between it and the female appears to be at an end; and it would be a new and rather anomalous fact in physiology to find a female attached to young for which she did and could do nothing. This would be an affection without an object; and though we find that the human race very frequently blunder into the exercise of such affections, we are not aware of the existence of one in the rest of nature. The affection of the male, or rather of the young for the male, is well established, and we can see its purpose. "I have been assured by the fishermen," says Mr. Yarrell, "that if the young were shaken out of the pouch into the water over the side of the boat, they did not swim away, but, when the parent fish was held in the water in a favourable position, the young would again enter the pouch." The female has no such protection to give them; and thus it would be important to ascertain whether the female has any attachment for the young or is perfectly indifferent to them.

The determining of this is a matter of no inconsiderable importance in a physiological point of view. The best portion of that labour which wholly devolves on the female in all other animals that bring their young to maturity, either by internal gestation, or by hatching, is, in the case of the pipe fishes, transferred to the male; and what we wish to know is, "Is the maternal affection transferred along with it?" This is a cross case—the very reverse of what usually occurs; and, therefore, if we could get complete information upon it, it would be an *experimentum crucis*, giving to our theories of the paternal and filial affections of animals much of the force of demonstration. To those who do not reflect upon the length to which a single well-established principle will often carry us, this may seem only a trivial matter; but it would afford an easy and ready key to many apparent anomalies that we meet with when we study the actions of animals, and even those of mankind, for the purpose of tracing them to their causes, the most important purpose for which we can study them.

The motions of this fish in the water are somewhat singular. Mr. Couch mentions, that "this species may be seen slowly moving about in a singular manner, horizontally or perpendicularly, with the head upwards or downwards, and in every attitude of con-

tortion in search of food, which seems to be chiefly water insects." How the food finds its way to the stomach is rather a puzzling matter, at least upon any of the ordinary principles of deglutition. The gape of the mouth can do little in this way, for it is very small, the pipe of the produced jaws appearing as if it could be half opened by a lid on the end, this lid being the lower jaw, which does not come so low as to be horizontal when the gape is distended, and the upper jaw inclines backwards. The mouth is not in any sense of the word a biting mouth, and it is capable of enclosing only a very small substance, without any apparent means of conveying it along the pipe. Mr. Yarrell says, "These *Syngnathi* are supposed to be able, by dilating their throat at pleasure, to draw their food up their cylindrical beak-like mouth, as water is drawn up the pipe of a syringe." This supposition is not satisfactory; and that for this obvious reason, that any one who looks at the tubular part of the mouth of a pipe-fish, and who has at the same time a knowledge of the principles of hydraulic action, would at once pronounce that this, if fit for acting as a syringe at all, is about as clumsy a one as could well be imagined. But Nature's machines are all the very best adapted to their purposes that can be made—that can be imagined, for nothing at all approaching to them can be made; and therefore there must be some other use than this of the singularly-formed mouths of those fishes, for which the said mouths are much better adapted than any other form of that organ which we can imagine. What this may be is a matter of observation, and not of any reasoning from analogy; for the fishes are so very peculiar that we cannot find an analogy that will rightly apply to them.

With the genus *Pegasus*, in which the mouth is differently formed, these fishes are distinct from all the rest as an order, and thus the elements of all our knowledge of them must be drawn immediately from observation of themselves.

We have mentioned that, as they begin to produce while yet very small, the size of these fishes cannot be admitted into the general description of them; but, as the proportions are nearly the same for all sizes, we shall thus quote Mr. Yarrell's very clear and accurate statement of these as being perfectly descriptive of the species. "From the point of the tubular mouth to the posterior edge of the indurated portion of the operculum, the length is, when compared with the whole length of the fish, as one to eight; if measured to the edge of the shoulder it is as one to seven and a half, and this proportion exists in individuals of various ages and lengths, from six inches to eighteen; from the mouth to a projecting point at the anterior edge of the eye, and thence to the pectoral fin, the distances are equal; the jaws united, tubular, slightly compressed; in depth but one-third that of the head at its deepest part, which is in a vertical line with the centre of the operculum; the mouth small, placed at the extremity of the tube, opening obliquely upwards; the lower jaw the longest; eyes rather large, bony orbits prominent; operculum covered with radiating striae; the head between the eyes flattened; behind the eyes rising into a keel-like crest, which reaches to the neck; from the pectoral fin to the anal aperture the body is deepest and heptangular, with three ridges along each side, and one along the abdomen, which ends at the vent; throughout the short length of the dorsal fin

the body is hexangular, the ridge on the abdomen being discontinued; thence to the end of the tail sloping, slender, and quadrangular, with a series of forty-four plates; the pectoral fins are small; the dorsal fin commences at two-fifths the length of the fish, and in a vertical line rather before the anal aperture; the largest rays are not equal in height to the depth of the body; the anal fin very small; the tail rounded and fan-shaped; there are forty rays in the dorsal fin; twelve in each of the pectorals, four in the anal, and ten in the caudal. The prevailing colour is pale brown, transversely barred with darker. It appears from the statements of the various authorities, that the numbers of rays in the fins are not quite constant. The colour also differs. It is always rather lighter, on the under side of the fish than on the upper, and in some specimens it is whitish.

Deep nosed Pipe-fish (Tylphe). This species belongs to the same section as the one already described; and its economy seems to be very nearly the same. It has pectoral, dorsal, anal, and caudal fins, and the male has the same kind of abdominal pouch for receiving the eggs when they are discharged by the female. As a British fish it is found on the same grounds as the other, and is not rare on many parts of the south coast, though we believe it is not found in so many localities as the other. It is usually found in the seaweed, or in the water near it, where the depth does not much exceed two fathoms.

It is easily distinguished from the former species both by its form and its colour. The pipe and mouth are much deeper in proportion, being nearly the same as the head, the outlines of which pass into those of the pipe without any angles or curves. It is also larger in proportion to the whole length of the fish; and it is considerably enlarged just at the end. Mr. Yarrell, who is by far our best authority respecting it as a British fish, says, "The whole length of the largest specimen which I have seen, is thirteen inches; from the point of the closed jaws to the posterior end of the indurated portion of the operculum the distance, compared with the whole length of the fish, as one to six; the head larger than in *S. acus*, and without the elevated ridge on the top of it; the distance from the point of the upper jaw to the projecting tubercle in front of the eye, and thence to the end of the pectoral fin, are equal; the united jaws are very much compressed, and nearly as deep as the head, only slightly inclining to a slope in front of the eyes; the body hexangular, the middle lateral angle on each side, becoming the upper angles of this quadrangular tail at the end of the dorsal fin. The fin commences further back than in *S. acus*, the middle of the dorsal fin being nearly the middle of the whole length of the fish; the series of indurated plates between the shoulder and the vent includes eighteen, thence to the end of the tail about thirty-seven, but both series are liable to a little variation in the numbers of the plates; the abdomen is almost rounded; the anal fin minute; the caudal fin pointed; the two central rays the longest, the others graduated. Fin-rays—Dorsal thirty-nine, pectoral fifteen, anal three, and caudal ten. The prevailing colour is olive green mottled with yellow brown and yellowish white.

Some other species having caudal fins have at times been described as British; but the probability is that they have been either one or the other of these. The early period of life at which these fishes are capable

of breeding, renders them liable to many mistakes as to the species of these fishes. Indeed their whole character is so full of anomalies, that nothing can with safety be stated respecting them, unless it is borne out by the facts as established by the most careful observers.

2. *Syngnathi*, with a dorsal fin only. The species *Acus* which we first noticed, has sometimes been called the "Sea Adder," but these of the section which we are now to notice, have much more of a snake-like shape, in consequence of the absence of all the body fins answering to the extremities of ordinary vertebrated animals, and also the caudal fin. They of course swim by means of the flexures of the body, as the dorsal fin is not a propelling organ, but merely a steadying one, by means of which the effect of the portion of the body behind it is increased. The males in none of the species of this section have subcaudal pouches for the reception of the eggs, but still they hatch them on the same principle as the others, though not exactly in the same way. They are placed upon the abdomen of the male before the vent, each being lodged in a separate depression which is in the form of a segment of a hollow sphere; and to this the egg is glued by its own gelatinous capsule until the young fish is matured. The eggs of these of the former section, are also each lodged in a depression, or made to adhere to it, and not left loose in the pouch with only the protection of the two leaves that close it. This is also the case in the marsupial mammalia; for when the young are transferred to that abode in a rude and formless state, each adheres to its seat independently of the pouch, and the pouch is only an additional protection. In the marsupial animals, we believe there is a relation between the development of the parent and that of the young when discharged from the internal uterus, these being always nearer its maturity in those species that have the pouch the least developed. We are not aware whether the two sections of the pipe-fish follow the same law, and whether the eggs remain a shorter time attached to the male than in those with the pouch, but it is probable; we are certain that the young of the pouchless ones can find no place of security in the body of their parent, after once they come out of the egg. The difference of time, if any, in the hatching of the eggs of the two sections, is a point well worthy of being ascertained, as a sort of connecting link in one of the most obscure portions of physiology. The eggs of these fishes are not the only ones that are hatched in depressions on the body of the parent animals; for the eggs of the Surinam toad are hatched in the same manner, only it is on the back of the female, the intermediate parts of which swell up and form lodgments for the eggs as long as it is necessary for them to be there. To what extent the integuments of the abdomen of the males of these pipe fishes swell up so as to afford a protecting lodgment for their eggs, has not been observed, or, if observed, not stated.

One cannot help being struck with the beautiful provision of nature in the place and mode in which the eggs of the two sections of pipe-fishes are hatched; as well as with the different forms of the tails as making part of this provision. The tail of a fish from the dorsal fin backwards, is the portion of it which has the most severe action in swimming; and if there is no caudal fin, more motion of the tail would be necessary to give the same impulse to the body than where

there is one. The first section of the pipe-fishes have caudal fins, and the second have none, therefore the second must exercise the tail more vigorously in swimming than the first. Therefore again, the eggs are far more safe on the under side of the tail in the section which have a caudal fin than in the section which have not. But still, even with the fin, the tail has too much motion for the perfect safety of the eggs, without the protection of the pouch; and they are furnished with that protection accordingly. The body anterior to the vent, which contains all the organs of the vital, nourishing, and reproductive systems of the fish, does not partake in the rapid action of the tail as an organ of motion; and therefore the eggs placed upon it are secure enough in the depressions of the body without the addition of a pouch.

Thus far we can understand the meaning of the different organisation of the two sections of these very curious fishes; but here the chain of our investigation breaks off; for we want all the information that, could we obtain it, would enable us to connect these fishes with the rest of the system of nature, so as fully to understand the part which they act in the general economy of the whole. In nature, all animals are useful, not for what they produce as for what they consume; and when we find one framed and organised upon a plan widely different from the majority of the others, we may, in general, be assured that the one so formed has an office to perform as curious, and as much out of the ordinary way, as it is itself. But the whole of these fishes is peculiar. They are peculiar in their very skeletons; for they are not bony fishes properly so called, neither are they cartilaginous. They in some measure partake of the characters of both, and the result is a character which does not agree exactly with either. Their fins, when they have them, resemble the fins of the true fishes; and the coverings of their bodies are more analogous to those of the cartilaginous ones. Their gills are intermediate both in structure and in action; and so, notwithstanding its peculiarities, is the mode of their re-production. The singular form of the body, and the still more singular formation of the mouth, point out a very peculiar kind of food and manner of getting at it; but it is exactly at this point that our information breaks down; and we call upon the admirers of nature in its working state to tell us, "What is the particular use of the pipe-fishes?" At present, there are no data from which to deduce anything like a satisfactory answer to that question; and therefore we have no alternative but to wait till more knowledge shall be acquired, and, while we do so, make the most of the works of which we are in possession, which carry us very little farther than the mere discrimination of a few of the species,—to which species, in this second section, we shall now very briefly advert, confining ourselves to such as have been met with on the shores of the British islands; as it is by attending to them that we have the best chance of increasing the volume of our information.

Æquorial Pipe-fish (S. æquoreus). The specific name given to this species would lead to the conclusion that it is more a fish of the plane or open sea than the others; and in corroboration of this we may remark that, as a British fish, it is much more rare on any one part of the coast than either of the species already noticed, but that it has been found occasionally at more points. Either, or both, of the fin-tailed species may be obtained, with a very great degree of

certainly, by fishing for them in certain parts of the channel; but there is no place where the capture of a specimen of the present species could be calculated upon with any thing like certainty. It was mentioned as occurring in Scotland by Sir Robert Sibbald, whose *Scotia Illustrata* appeared in 1684; but though Sir Robert is correct in the main, there are certainly doubts as to some of the animals which he enumerates. The silurus is one of them, and it may be that this pipe-fish is another, the more so that none of the specimens which have been found in recent times have been of nearly the dimensions which he assigns; namely, two feet in length. The best account that we have of it is from Colonel Montagu, who obtained his specimens on the south coast; we shall therefore quote what he says of it: "Length twenty inches and a half, viz., ten to the vent, and ten and a half to the end of the tail." "The length of the head," adds Mr. Yarrell, "is to the whole length of the fish as one to twelve; the most similar form to that of *S. acus*; its length to the eye three quarters of an inch; from thence to the end of the gill, nine; including the eye, one inch (which gives the head a little, but a very little, more length than Mr. Yarrell's proportion, which is sufficiently near the truth for ordinary purposes). The form of the body is rather compressed and angular, with an acute dorsal and abdominal ridge, which, together with three slight ridges on each side, give it an octangular appearance; it is of equal size from the gills to the vent, which part (that between the gills and the vent) contains about thirty plates; from the vent to the extremity of the tail it is at first quadrangular, and toward the end round and taper, containing about thirty plates: immediately behind the vent the body of this specimen suddenly decreases to one-third less in diameter; but this may be a sexual distinction.

"The dorsal fin consists of forty rays, commencing in a vertical line considerably in front of the vent, and terminating behind it, so that three-fourths of the fin is before the ventral aperture. The end of the tail is extremely small and compressed, the rays of which are not visible to the naked eye. The colour is yellowish, with transverse pale lines and dark margins, one in each joint, and another down the middle of each plate, giving it the appearance of possessing double the number of joints that it really has; these markings, however, cease at the vent."

Various testimonies unite in proving that this is a more pelagic fish than either of them which we have noticed as belonging to the first section. Mr. Couch, notwithstanding all his wits, and all his industry in "willing fishes from the flood," has hitherto been unable to obtain more than two specimens of this one; but the channel fishermen report, that about thirty or forty miles from the land, and in a depth of not less than fifty fathoms, it is very commonly seen in fine weather, swimming near the surface. It is also, according to the accounts, much more abundant near the channel islands than toward the shores of the mainland of England. It does not, indeed, appear to come so regularly to the shallow water for physiological purposes as the fin-tailed species; but we are still in want of many of the elements which are necessary for obtaining a satisfactory history of it. There is one circumstance in the form of this fish which is worthy of attention, the more so that it is common to some others, though not to the whole of the division. The part of the body from the gills to

the vent, which is of nearly equal diameter for its whole length, is capable of very little flexure; and the sudden diminution in thickness of the tail after this enables that organ to move from its base with much more freedom and less disturbance of the anterior part of the body, than if the taper were more gradual. This allows a sort of repose to that portion of the animal which contains the vital organs, and also which bears the eggs, whether in the interior of the female, or on the exterior of the male, while the tail is at perfect freedom to impel the body through the water. Thus, comparatively finless as it is, this species appears to be better adapted for free swimming in the under-sea, than those members of the family which are the most amply provided with fins, and which, on a cursory view, we should be apt to regard as the best swimmers.

Snake Pipe-fish (S. ophidion). This is the most snake-like in its form of the whole race. The tubular portion is long and slender, the head very small, the body also small, but of uniform thickness to the vent; the tail is very long and slender, and tapers to a very fine point, or rather it tapers till it becomes exceedingly slender, and then the tip of it is slightly enlarged and compressed. Slenderness is indeed the remarkable character of this fish; for in a specimen a foot long no part is thicker than an ordinary goose-quill. The tail behind the dorsal fins is considerably longer than the body and head; and as about a fourth of the fin is in rear of the vent, that portion also must be considered as belonging to the tail. The body appears to be much less angular than in most of the other species, by the longitudinal rays being nearly obliterated, and the junctions of the plates on the sides of the body are also very indistinct. So far as the vestiges of the ridges can be traced, the body is octangular in the section, with one ridge on the back, another on the belly, and three upon each side. The colour is a pretty uniform olive green, without any cross bars or mottlings. The irides of the eyes, which are rather prominent, are red, and the pupils black.

There is no vestige of a pouch on either the female or the male, but the latter has depressions on the abdomen for receiving the eggs, which do not appear to be matured till the early part of the autumn. This appears to be a discurative species as well as the preceding; and though specimens have been taken near the land, it has been in the free water, and where that water had a current. It has been mentioned as occurring both in the northern and the southern seas of Britain, although most frequently in the latter; but every where it is comparatively a rare species. Twelve or thirteen inches is the greatest length of any that have been described; and it is curious how so light and slender a thing can endure so well as it appears to do the violence of our seas in their most turbulent state. The probability is, that these, like all the more slender fishes, retire to a depth below the vibration of the waves in all cases of storms, for they are seen swimming over the surface only when the weather is fine and the sea tranquil.

Worm-shaped Pipe-fish (S. lumbriciformis). This is the smallest of all the British *Syngnathi*; and though it agrees with the rest of the section in all its more general and essential characters, its appearance and manners are somewhat different. It is seldom more than between five and six inches in length, and

smaller in the thickest part of the body than an ordinary earth worm. The tubular part of the mouth is shorter than in the others, and curves upward at the extremity. The head is rather large, and the thickest part of the body is near the head, from which it tapers uniformly to the point of the tail. The head, from the point of the snout to the posterior edge of the operculum, is one-twelfth of the whole length; the head and body to the vent make only a third of the length, leaving two-thirds to the tail; three-fourths of the dorsal fin are on the tail, and only the first fourth on the body. There are about nineteen plates on the side in front of the vent, and as many as fifty on the tail. These plates are but little conspicuous; and the longitudinal lines are almost wholly obliterated, so that the section of the body is nearly circular; the surface is also smooth; the colour is dark olive green. This species is a shore fish, and not a pelagic one. Its habits are lurking, and it is usually found under stones. It is met with on various parts of the coast, and even in the northern islands: and in some places of the south it is reckoned very common.

HIPPOCAMPUS—Sea-horse. The fishes of this genus are even more singular than the *Syngnathi*, both in their appearance and their habits. They have the body much compressed and very considerably deeper than the tail, to the thickness of which the posterior part of the body is reduced by a very rapid curve, which, for a reason afterwards to be explained, is much more conspicuous in the female than in the male. The depth of the body is also much contracted toward the head, which, with the enlarged operculum and the elevated angular plates on the head behind the eyes, gives the fish the appearance of having a true neck as in mammalia and birds. This part is also much more flexible than in any other fish, so that the head can be moved upon the body, and thus become, by means of its angular and spinous projections, an instrument of prehension, by the help of which the fish can climb. This flexible portion is not a neck, however, but a part of the body, for the pectoral fins are in advance of it, and when they are exerted they have something the appearance of ears. The tubular part of the mouth is very slightly bent upwards, and the gape oblique and very small. The eyes are prominent, and the widest part of the head is across them, the crest behind being compressed, so that when seen in front it has the appearance of an ornamental crest set on the head rather than belonging to it. There are two spiny elevations immediately over the eyes, and the pectoral fins look like ears placed immediately behind. The general profile of the head is of a triangular shape, and in the female the crest toward the hind head rises higher than in the male. The body and tail are angular, with prominent longitudinal ridges, which are crossed by other ridges at the junctions of the plates, extending round the body, and forming little projecting knobs where they cross the longitudinal ones. Both sexes have dorsal fins as well as pectorals, the dorsal being wholly or nearly in advance of the vent; the female only has a small anal fin, and neither have any ventral or caudal. Indeed the tail is more completely finless in them than in the *Syngnathi* which have no caudal; for these have the dorsal in part upon the base of the tail. The tail is prehensile, and can twine firmly round the stems of seaweed, or other small substances, its hold being rendered more firm by the

ridges and tubercles with which it is beset to the very tip. What with the prehensile tail, what with the flexibility of the anterior part of the body, and the angular projections on the cheeks, these animals are not badly adapted for climbing. They can hold on with the tail, and advance the body to its whole length, hold on with the head, and again bring up the tail, so that they can clamber about among the seaweed something in the style of the small climbing *Sauria*. It appears also that they can make use of the unbending of the body and tail to give them a rapid impetus through the water, in the same way that an impetus is obtained by lobsters and various other leaping crustacea.

When they are dead, the body does not become relaxed and straight as it is in most fishes. The middle, where the dorsal fin is situated, bends slightly inward as seen in profile; and the flexible part of the body bends in a curve toward the belly, till the axis of the head is enclosed at considerably less than a right angle to the axis of the body. The tail also coils up into a spiral, toward the lower side of the fish; and the bending both of this and of the anterior part are in the mesial plane of the body. This, with the angular projections on the body which give it the appearance of being made up of a series of flat plates, soldered together at the ridges both longitudinal and crosswise, make it look very unlike any ordinary fish, and thus it is in request by collectors of natural curiosities.

When in this bent or curled state it has, whether viewed in profile or in front, some faint resemblance, in the head and neck, to the same parts of a horse, which is the cause of the name given to it. In the profile the male has most of this resemblance, as the posterior part of the head is not so deep in the section as in the female. In both the curved part of the body, as far as the commencement of the dorsal fin, has a good deal both of the outline and the peculiar curve of the neck of a horse; and the front view has perhaps more of this fanciful likeness; but here the resemblance ends, and the portion to the rear of the dorsal has much more resemblance to the tail of a saurian reptile.

The mode of reproduction has not been actually observed; but from the structure of the animals, both internal and external, there is no doubt of its being in principle the same as in the *Syngnathi*. The females are at once distinguished from the males by the more prominent outline of the belly, its more rapid contraction posteriorly, and the presence of a very small anal fin near the angle at which the under line of the body meets that of the tail. The specimens having this form have been ascertained to be females, by the fact of their containing ovaries and roe. The males have the under line much less prominent, and at the part corresponding to that where it begins its sudden curvature toward the base of the tail in the female, there is in the male a sort of pouch consisting of two side lobes, not with ridged plates like the rest of the body, but smooth and flexible; and there can be no doubt that these form a pouch in which the eggs are hatched, in a manner similar to that in the first section of the *Syngnathi*. This pouch is so situated that its contents are well protected from injury from the motions of the fish; they lie in the deep angle formed at the posterior part of the body, and still there is enough of the tail left free beyond the pouch for all the purpose of swimming and prehension.

There are various species of *Hippocampus*, some found in the seas of Europe, and others in the seas of the south and east. Some of those of the warmer seas have the tubular part of the mouth much larger than those of the European seas; and some of them have filaments at the muzzle and on other parts of their bodies, which increase the singularity of their appearance. A large species which is found in the Australian seas has various parts of the body furnished with appendages in the shape of bows, the use of which is not known; indeed we know but little of the economy and habits even of the one which is occasionally found upon our own shores. That one is,

The Short-nosed Sea-horse (H. brevisrostris). This is not very often met with on any of the British shores; but the more southerly the place, there is the greater chance of finding it, though the chance is so small that one need hardly risk the getting of it as an adventure to be undertaken on purpose. It appears to occur most frequently on the shores of the Channel isles; next to that on the Channel coast of the main land, and more rarely in the Bristol Channel and on some parts of the coasts of Norfolk and Suffolk; but we are not aware of its occurrence in the northerly parts of the island.

It is a very small fish, none of the specimens obtained in this country exceeding five inches in the total length; and, when they are curled up in the state in which they are commonly exhibited as museum specimens, they are not above half that length. The tubular portion of the mouth is much smaller in both its dimensions than the remaining part of the head. The eyes are very prominent, with the irides of a straw yellow; and the spinous tubercles over them have much the appearance of little horns; the pectoral fins are immediately in the rear of the gill-cover, rather small, and containing about eight rays in each; but they are capable of being erected and spread out, so as to be conspicuous for their size; the section of the body is seven-sided, one of the sides being on the back, and continuous from the nape to the tail; thus, there are three ridges shown upon each side, and one upon the belly; this and the one next to it on each side merge at the posterior part of the abdomen; and the tail is quadrangular or flat, or bare below, and on the sides with four ridges; this is different from those *Syngnathi* which carry the eggs before the vent, for in them the ridges next the back merge in the continuation upon the tail; on the body the cross ridges, or transverse segments of the plates, are eleven in number, with the tubercles at the intersections rather prominent; and the number of segments on the tail is about thirty; the dorsal fin, which is rather higher in the female than in the male, contains about sixteen rays; and the anal fin of the female, which is very small, not more than four; the general colour is pale brownish-ash; but there are traces of blue upon some parts of the body; and in the living fish there is a beautiful play of prismatic colours, which fades when the fish is sickly, and goes off entirely after it is dead.

If its food were known, which it is not, this would be one of the most amusing of vase fishes, as its manners are so different from those of any other of the species. The golden carp, which is our principal vase fish, is pretty enough; but it has nothing to recommend it save its colour and the ease with which it can be kept in a state of confinement in fresh water. The sea horse, or indeed any of the family to which

it belongs, is never found but in the sea; and thus it could not, in all probability, be kept, unless in situations where it could have regular changes of sea water. But where this could be had,—and it is probable that, if taken from places where the fish is found, it would in all likelihood contain the requisite supply of food,—there is no doubt that this fish could be made an amusing addition to the living collection, as well as a source of mere wonder at its form in the dead one. Specimens found upon different parts of the British coasts have been kept alive long enough to show that they are any thing but tender of life. Indeed we might come to the same conclusion *a priori*, by attending to the structure of the breathing apparatus, which gives the air so little access to them, that the fish must, according to the general analogy of all fishes, live for a long time out of the water, as compared with fishes to whose gills the air has ready access. We do not know the quantity of respiration which those fishes with tufted gills require, as compared with such as have them free and pectorated; but there is every reason to believe that it is less; and thus the water in which the fishes were kept would require to be less frequently changed. Mr. Lukis, of Guernsey, who supplied Mr. Yarrell with specimens of these fishes, of which figures are given in Mr. Y.'s work, and also with every valuable information, gives the following account of their manners in a state of confinement:—"At the time of writing, June 9, 1835," says Mr. Yarrell, "Mr. Lukis had two female specimens of *Hippocampus brevirostris*, then healthy and active, which had been hung in a glass vessel, and their actions were equally novel and amusing. 'An appearance of search for a resting place induced me,' says Mr. Lukis, 'to consult their wishes by placing sea-weed and straws in the vessel; the desired effect was produced, and has afforded me much to reflect upon in their habits. They now exhibit many of their peculiarities, and few subjects of the deep have displayed, *in prison*, more sport or more intelligence. When swimming about, they maintain a vertical position; but the tail is ready to grasp whatever meets it in the water, quickly entwines in any direction round the weeds, and, when fixed, the animal intently watches the surrounding objects, and darts at its prey with great dexterity. When both approach each other, they often twist their tails together, and struggle to separate, or attach themselves to the weeds; this is done by the under part of their cheeks or chin, which is also used for raising the body when a new spot is wanted for the tail to entwine afresh. The eyes move independently of each other, as in the chameleon; this, with the brilliant changeable iridescence about the head, and its blue bands, forcibly remind the observer of that animal."

This passage, short as it is, throws more light upon the character and habits of this very singular fish, than all the disquisitions of the systematic naturalists put together, and makes one heartily wish that there was a Mr. Lukis on every part of our shores. It establishes beyond a doubt that the chief residences of these fishes is among the sea-weed; and that they cling by their prehensile tails waiting for the very minute substances on which they feed, till they are brought within their reach by the motion of the water. They are thus enabled to hold on in places where no fish could hold on by the mere action of its fins upon the water; and we can see how well the flexibility of the anterior part of the body and the double action of

the prominent eyes, each taking in its own field of action, independently of the other, enable it to capture the smallest food in sufficient quantity for its support. What purposes the filaments and leaf-like appendages upon the species which are found in the tropical and southern seas may answer in their economy, we are unable to say. We cannot suppose that, like the barboles which are found upon many common fishes, they can in any way answer as baits or lures to attract the prey, for the fish itself is so small and its gape so narrow, that it cannot be supposed to feed upon any thing that could be lured by a visible bait. There is, however, no known limits to the smallness of the tenants of the deep, as they do not require any apparatus for bearing them up, as is the case with air animals; and thus the total volume of living creatures in the sea which are individually too small for our vision, may amount to more than that of all the visible ones, abundant as they are. It is only in this way that we can account for the subsistence of the countless myriads barely within the range of our vision, with which all parts of the ocean teem.

SOLENOSTOMUS (Tube-mouth.) This name has been given by some authors to one or other of the pipe-mouthed fishes (*Bouches en flute* of Cuvier), which are spinous finned fishes with pectorated gills, and spawning in the same manner as other fishes, whereas the one now alluded to (and there is only one known species) agrees exactly in its physiology with the rest of the present family. This one species has been confounded with the said pipe-mouthed fishes (*fistularia*), which are the long-bodied division of the *Bouches en flute*, while the name of this one has been given to the sea snipe of the Mediterranean, which is one of the oval-headed or *Contrisil*. In most of its characters, it agrees with *Hippocampus*; but instead of the pouch there are two large ventral fins in the rear of the pectorals, which form a sort of apron for retaining the eggs; there are also two dorsals, one just behind the head, and a smaller one near the origin of the tail, and there is a long and pointed caudal fin. It is found in the Indian seas, and is the *Fistularia paradoxa* of Pallas.

SYRPHIDÆ (Leach). A very extensive family of dipterous insects, belonging to the section *Athericera* of Latreille, having the proboscis long, membranous, or fleshy, elbowed at the base, terminated by two large lips, enclosing in a dorsal canal the organs of suction, which are four in number, the superior large and channelled beneath, in order to receive the three other slender organs, which are the representatives of the maxillæ and tongue; the palpi are two in number, and attached at the base of the maxillæ: the head is hemispherical, and occupied, to a large extent, by the eyes, especially in the males; its forehead or frontal part is often produced into a sort of muzzle or nose; the slender bristle of the antennæ is attached at the upper part of the third joint of these organs; the abdomen is often long and depressed. Many of these insects resemble humble-bees (see the article ENTOMOLOGY, vol. ii., p. 430, for comparative figures of the bee and one of the *Syrphidæ*); others resemble wasps. They are often of large size, and their colours variegated, some being metallic in their tints, varied with golden or white bands. They delight to rest upon flowers, the honied sweets of which they extract for their food. There is considerable diversity of form amongst the different species of which the family is composed; in

some the body is short and thick, in others long and depressed, and in a few the abdomen is very slender at the base, and clubbed at the end; the legs in some are very slender, whilst in others the hinder femuræ are thickened and toothed, and the tibiæ curved. The flight of these insects is also varied according to the species. Many of these insects delight to select some quiet warm spot in the open part of a wood or garden, where they may be seen hovering for a great length of time without shifting an inch from the spot, although their wings are in such rapid motion that they can scarcely be perceived. No sooner, however, are they alarmed or disturbed by the approach of some other fly, than they dart off with the quickness of lightning, returning again, however, in a very short time to the very same spot. In like manner they will select a leaf or a stone, from which they will make long flights, returning again to the identical situation.

There is considerable diversity in the economy of these flies. Although the observations hitherto made upon their habits have been but few in number, it has been ascertained that their eggs are deposited in the earth, in manure, in rotten wood, in the bulbs of ciliaceous plants, in the nests of humble-bees and wasps, on the leaves and stems of plants, in putrescent matters, and in water. The larvæ have the head fleshy and of a variable form; when full grown they do not throw off the outer skin, which becomes a covering for the pupa.

The number of species comprised in this family is very considerable; the genera are, *Ceria*, *Callicera*, *Chymophila*, *Aphritea*, *Ceratophyla*, *Chrysotoxum*, *Psarus*, *Miztemyia*, *Volucella*, *Tennocera*, *Sericomyia*, *Criorhina*, *Mallota*, *Eristalis*, *Didea*, *Platynocheta*, *Helophilus*, *Priomera*, *Palpades*, *Merodon*, *Tropidia*, *Senogaster*, *Xylota*, *Brachypalpus*, *Syritta*, *Eumerus*, *Rhingia*, *Graptomiza*, *Brachyopa*, *Pelecocera*, *Milesia*, *Syrphus*, *Doros*, *Sphærophoria*, *Ocyptamus*, *Cheilosia*, *Chrysogaster*, *Orthonera*, and *Paragus*. The most interesting of these genera are described in their places in alphabetical order.

The genus *Syrphus* is distinguished by having the abdomen narrowed from the base to the extremity; the frontal projection of the head is short, the wings are apart when at rest, and the posterior margin of the exterior cell of the wing is nearly straight, or but little sinuated. The larvæ of this genus feed upon plant-lice, and it is very interesting to observe the carefulness with which the female *Syrphus* flies around the twigs of various garden shrubs, inspecting each minutely, for the purpose of discovering whether there are any of the *Aphides* upon the plant. In case any are discovered, the insect, still remaining on the wing, turns herself round and deposits an egg in the midst of them, attaching it to the twig or leaf; from this egg an unsightly grub, without legs, is hatched, which is no sooner born than it commences its voracious attacks upon the insects in the midst of which it finds itself; destitute of eyes, it gropes about with the extremity of the body, until it feels one of its luckless victims, which it immediately seizes upon, by means of the acute points with which its mouth is armed, and raises it aloft in the air, holding it in that situation until it has completely extracted all the fluid from its body, and then casts it away; it then proceeds in the same manner, having little occasion to move from the spot, and consequently being destitute of legs. When it has attained its full size it

fastens itself by the hinder part of the body to the twig; it then contracts its body, which by degrees assumes an oval form without casting the outer skin, which serves as an envelop for the inclosed pupa. The perfect insect makes its appearance in a very short time, having lost all the voracious propensities of its former state. We have found it very serviceable to introduce the larvæ of these insects amongst the *Aphides* which have infested a choice plant, and which they have cleared in a very short time. There are about thirty British species of this genus.

TABANIDÆ (Leach). A family of dipterous insects belonging to the division *Brachocera*, and forming the subdivision *Heracheta* (see *DIPTERA*). These are large two-winged flies, well known for their tormenting powers in attacking horses and cows, by sucking their blood by means of their powerful proboscis, composed, as the subdivisional name indicates, of six lancet-like organs, inclosed in the ordinary fleshy rostrum, which is terminated by two large fleshy lips. The eyes are large, especially in the males, and the antennæ have the third joint large and crescent-shaped, terminated by several smaller articulations. A figure of the head of one of the species of the genus *Tabanus*, with all the parts of the mouth disengaged from the rostrum, is given in the article *DIPTERA*, and the details of the mouth in the same genus are given in detached figures in the article *INSECT* (vol. ii. p. 850, fig. 88). These insects have often been described under the name of gadflies. The body is seldom very hirsute; the head is of the width of the thorax, nearly hemispherical, and covered, except a narrow space, especially in the males, by two large eyes, which, in some of the species, exhibit the most brilliant hues when alive, the colours being arranged in bands. The wings are extended horizontally on each side of the body when at rest; the winglets are large, and nearly conceal the halteres; the abdomen is triangular and depressed; and the tarsi are terminated by three pulvilli.

From the comparatively large size of these insects, they are capable of inflicting very great pain both upon men and beasts of the fields. Their flight is noiseless, although some make a buzzing sound when on the wing; and often, whilst walking in the fields and woods, we have been made to start by the sudden pain produced by one of these insects which had settled upon the naked hand. Their pertinacity is also so great that they cannot be driven away. The horse lashes with his tail and throws about his head, but all in vain; the *Tabanus* retains its seat, and at length, when satiated, the fly desists; and then the sides of its victim may be seen trickling down with blood from the wounds made by the insect. It is supposed that the redoubtable *Zimb* of Arabia, or *Tsaltsalpa* of Bruce, is a species of this group of flies. The *Tabanus maroccanus* of Fabricius attacks the camel, which, according to M. Desfontaines, is sometimes entirely covered with these troublesome creatures. It is a curious fact that the females alone are endowed with these blood-thirsty qualities, the males frequenting flowers.

The larvæ of *Tabanus bovinus* reside in the ground. They are long, cylindrical, narrowed towards the head, which is small, and armed with two hooks. The segments of the body, twelve in number, have elevated transverse ridges. The pupæ are naked, nearly cylindrical, with two tubercles in front, the

margins of the segments serrated, and six points at the posterior extremity. By the assistance of the serrated points of the segments of the abdomen, the pupa makes its way immediately before its final metamorphosis to the surface of the ground, where it protrudes the fore part of the body into the air. According to Fabricius, the larvæ of *Chrysops* also reside under ground, and those of *Hæmatopota* in dung.

The genera are : *Pangonia*, *Dicrania*, *Rhinomyza*, *Tabanus*, *Diabasis*, *Acanthocerus*, *Hæmatopota*, *Hexatoma*, *Chrysops*, *Silvius*, *Raphiorhynchus*, and *Acanthomera*, the three printed in italics being inhabitants of this country. The genus *Pangonia* is especially distinguished by the great length of the proboscis, which, in some species from Georgia, in America, and Nepaul, are more than twice the entire length of the body. *Tabanus* is distinguished by its short thick proboscis, and by the emarginate structure of the third joint of the antennæ. The species are very numerous, and are found in almost all parts of the world. The type of this genus is the *Tabanus bovinus*, Linnæus, a large handsome species, an inch long, with the body brown above, grey beneath, eyes green, tibiæ yellowish, and with transverse lines and triangular spots of pale yellow on the abdomen. The wings are transparent, with reddish-brown nerves.

TABERNÆMONTANA (Linnæus). A genus of tropical trees and shrubs, mostly ornamental; the flowers are sweet-scented and pentandrous, and the genus ranks among the *Apocynææ*. The species are favourite stove-plants, are grown in light loam and heath mould, and are increased by cuttings rooted in sand.

TACHINA (Meigen). A very extensive genus of dipterous insects belonging to the family *Muscidæ*, having very much the appearance of common flies, with the body narrow, or of moderate width; the face a little oblique; the antennæ reaching to the epistoma; the second joint elongated, and as long, or nearly as long, as the third; eyes naked; abdomen cylindrico-conical, ordinarily destitute of bristles in the middle of the segments. This very numerous genus comprises various species of *Muscidæ*, the larvæ of which are parasitic in the bodies of caterpillars, in the same manner as the *Ichneumonidæ*. The genus, in fact, may be regarded as the type of a still more extensive group which M. Macquart has named *Tachinarieæ*, and Robineau-Desvoidy *Entomobiæ*, all of which exhibit the same parasitic habits. The food of these insects, which they obtain from flowers, has far less influence upon their habits than the cares for their progeny. They deposit their eggs upon the outside of different insects, especially caterpillars; and the larvæ, as soon as hatched, burrow into the body, and there find a supply of food, taking care not to touch the vital parts. Lepidopterous larvæ are especially liable to the attacks of these insects, and our breeding cages are sometimes filled with a swarm of these flies, instead of some scarce moth or butterfly which we had hoped to rear. The type of the genus is the *Musca larvarum* of Linnæus.

TACHINIDÆ (Mannerheim). See *BRACHELYTRA* and *TACHYPORIDÆ*.

TACHYPORIDÆ (MacLeay). A family, or rather a subfamily, of coleopterous insects belonging to the division *Brachelytra*, and corresponding to the two tribes *Tachinidæ* and *Aleocharidæ* of Mannerheim. The chief character of this family consists in

the small size of the head, which is immersed in the thoracic cavity as deep as the eyes, without any distinct neck; the thorax is broader behind than in front; the body is of a moderate length, or is somewhat elliptical; the mandibles without teeth; the clytra often cover a considerable portion of the abdomen. They chiefly reside in fungi or dung. They are very active in their motions, and are occasionally prettily varied in their colours.

The chief genera are, *Lomechusa*, *Tachinus*, and *Tachyporus*. In *Tachinus* the tibiæ are spinose, the antennæ gradually thickened, and the palpi filiform. The *G. tachyporus* differs from the latter chiefly by having the palpi terminated by a small conical joint. The species are numerous and of small size.

TAGETES (Linnæus). A genus of South American annual herbs, belonging to the natural order *Compositæ*. Some of the species have been long cultivated as tender annuals; that is, raised in a hotbed in the spring, and transplanted into the open borders in May and June. The French and African marigolds are two of the most common.

TALIERA (Martius). The *T. Bengalensis* is a magnificent palm, native of India, where it was found by Roxburgh, and by him called *Corypha taliera*. In our collections they require to be kept, potted in light soil, in the warmest part of our stoves.

TAMARINDUS (Linnæus). A genus of large and handsome trees, natives of both East and West Indies. The flowers are monadelphous, and the genus belongs to *Leguminosææ*. These trees are celebrated for the excellence of their fruit, being medicinal as well as dietetic. The woods and jungles of the Coromandel coast are thickly studded with these magnificent trees, yielding almost at all times their delicious fruit. The pods hang long on the tree after the pulp is ripe. In our stoves the plants are kept in a diminutive state, and may be increased by cuttings.

TAMARISCINÆÆ. A natural order comprising only one genus, namely, *Tamarix*, of which there are six species. The species are chiefly shrubs or perennial suffruticose plants, with rod-like branches, small, entire, alternate, scale-like leaves, usually glaucous, diaphanous at the apex, and without stipules. The inflorescence is in racemes or spikes, and the flowers regular and united. The calyx is four or five cleft, persistent, and imbricate in æstivation. Petals attached to the base of the calyx, and equal in number to its divisions, and also imbricate in æstivation. Stamens equal in number to the petals, or twice as many filaments, free or monadelphous; anthers two-celled and burst longitudinally. Germen superior, free. Style short, and stigmas three. The species are natives of Europe, Asia, and Africa. Some of the kinds have an astringent tonic bark, and yield, when burnt, a large proportion of sulphate of soda. It is stated that it is a species of *T. gallica*, which produces that peculiarly saccharine and gummy matter known as the manna of Sinai. The species thrive in any soil, and are propagated by cuttings put in the ground either in autumn or early in spring.

TAMEÆ. A natural order containing only one genus; viz., the *Tamus communis* (black briony), and two species. They are climbing herbaceous plants, having very large tubers, whence the roots and stems are produced. The leaves are cordate, flowers axillary, in racemes small and white, succeeded by red berries, and common in British hedges. Qualities dangerous

TANACETUM (Linnaeus). A genus of hardy herbaceous perennials and evergreen shrubs; two of the former are British, and cultivated as pot or medicinal herbs, under the name of *Tansy*. The genus belongs to *Compositæ*, and is common everywhere.

TANAGER (*Tanagra*). A numerous genus, or rather group or family, of birds, belonging to the *dentirostral* division of Cuvier's *Passeres*, and placed in the system between the fly-catchers and the thrushes, with each of which they have some characters in common, though there is still enough that is peculiar to entitle them to be ranked as a distinct group, and so much diversity as to require separation into a good many subordinate genera. The progressive history of the group is by no means clear; so that, upon consulting the succession of authors that have alluded to them, it is not easy to say what is a tanager and what is not.

The general characters of the group are: the bill conical, triangular at the base, slightly arched in the culmen, and with a notch toward the tip; the wings short, and the birds taking only short flights. In their habits they more nearly resemble our finches than any other family of our birds. They feed upon seeds and berries, and also upon insects. The greater number of them are remarkable for the brilliance of their colours. In this also they agree with our finches, which, though sober in their attire as compared with the tanagers, are yet among the gayest of our little birds.

The more particular characters which may be regarded as applying most perfectly to the typical species are these: the bill with a ridge on the culmen, which makes its section nearly triangular at the base; the culmen a little arched; the upper mandible slightly notched, and very sharp at the tip; the lower mandible straight, but a little enlarged and convex in the lower outline toward the middle part; and the tomia of both mandibles rendered very efficient for breaking and bruising, by being bent inwards so as to form a margin; the bill is thus a very powerful and efficient one for its size, and it has much more of a granivorous than of an insectivorous character, though the notch shows that it does, to some extent, partake of the latter. The nostrils are lateral near the base of the bill, pierced in very slight nasal grooves, and partially covered by the reflected feathers of the front. The feet are of mean length, with four toes, three to the front, and one to the rear; the middle front toe as long as the tarsus, and united to the external one at its base; the inner one is entirely free. The wings of mean length, and rounded; the first quill shorter than the second; and the third the longest in the wing. As has been hinted, the flight is short, and the birds are not given to extensive migration, though many of them alter their habitation with the seasons. In this also they have some resemblance to our finches; for, when they are in the woods and thickets during the breeding time, they are mostly dispersed in pairs, whereas they sometimes flock when they come abroad to reap their harvest in the more open places.

All the tanagers properly so called are natives of the American continent, chiefly of the tropical, or at all events of the warmer parts, and it is as such that they are peculiarly characteristic of South America, which rivals, in the numbers and the splendour of its feathered inhabitants, the oriental islands, and all the richer districts of the East; and in the humming-birds,

the cotinges, and the tanagers, the one part of the world stands much on a par with the other. In the birds of paradise, the nectar-suckers, and the rollers, as is the case with the finely-coloured birds of tropical Asia, we cannot find any parallel among the birds of our comparatively cold climate that can be compared with those painted children of the sunny lands. This we could not expect; for the birds are characteristic of their native countries exactly in those very particulars in which those countries differ from our own, and the birds are among the means which we must use in seeking to obtain a knowledge of the countries which they inhabit.

They prefer the thickets on the margins of the forests, rather than the depths of the forests themselves; and in this again they resemble our finches, which are bush birds rather than tree ones. At one season of the year they find an abundant supply of food in the berries which those bushes yield, and in the seeds of various herbaceous plants with which the thickets are entwined; but when the supply there fails, they approach the cultivated grounds and the dwellings of the country people, often levying heavy contributions on the crops. When they come to the more humid and fertile places they perch upon the tops of the lofty trees, in order to be safe from the attacks of the numerous reptiles; as, were they to repose on the ground or on the bushes and low branches, the brightness of their colours would speedily disclose them to those snakes which are such destroyers of birds.

As is the case with most of the richly-coloured birds of tropical countries, few of them have much music in their voices; but there are some songsters among them, and the few that are, are much prized by the people of a country where birds are so many, and singing birds so few. Their nests are in general elaborately formed, constructed externally of small twigs and bits of stalks, and lined with wool, feathers, or down. They are of a hemispherical form, and the birds labour at the construction of them with the most indefatigable industry. The eggs in a hatch are but few, not exceeding two or three in number; but in most parts of the country they breed at least twice in the year. This double hatch in the twelve months is very common among the birds of tropical countries, whether the eggs in the hatch be few or many; and it is remarkable that the birds retain this instinct long after they have been naturalised in countries very different from their original one. We have an instance of this in our common domestic poultry, which there is little doubt came originally from the south-east of Asia; for though, by artificial treatment, they may be made to breed at almost any time, they have a natural tendency to breed in the spring and the autumn.

We can understand why the breeds of such birds as the tanagers should be less numerous than those of our finches and linnets, just as the latter are, generally speaking, less numerous than those of the warblers. The days are long with us at the time when our little birds have their most severe labour, that is, when they have to feed the young; while in the tropical regions the days are but little more than twelve hours, and the twilight is comparatively short, in consequence of the sun's rays descending almost perpendicularly, and consequently much sooner getting to that depth below the horizon at which twilight ends than when his course is more oblique.

Thus, as compared with the warblers, the finches and analogous tribes have really much more labour in finding food for their young, as the substances which they collect have to be gathered from a wider pasture, and are in themselves less nutritious. The eggs of our finches average about five in a hatch, and the tanagers two or three, which brings the annual productiveness of the two races very nearly to an equality. The eggs of the tanagers have some resemblance to those of the finches. They are oval, without any definite pointedness at the narrowest end, of a white ground, more or less greenish or bluish, and mottled with small spots of brown, or russet. The birds are also about the size of our finches and linnets, or perhaps in some of the species a little smaller; and they are neatly and firmly made, and very energetic in their manners.

When it is mentioned that the species of these birds amount to about sixty, it will be readily understood that there must be a considerable difference in their haunts and the details of their habits. Differences of species among birds or any other animals are not given to them for the sake of mere variety or distinction, but for adapting them to the performance of different offices in the grand economy of nature. It is true that, especially in the finer shades, we do not see the difference in the object and use; but this does not in the least affect the universality of the principle, which holds equally in the case of the most minute difference as of the most conspicuous, and equally in those cases in which we are unable to see it as in those of which we can easily give a full and satisfactory explanation. It is of very great consequence to us to bear this always in mind, and never to pass over the slightest difference of appearance without endeavouring to ascertain the cause; for if we pass over these minor matters in a careless manner, the habit is fostered by our natural love of indolence, and we are certain to be, or to become, equally careless in matters of more importance.

Upon this principle, it would be absurd in us to suppose that there could be sixty species of tanagers in the same regions of South America, all inhabiting precisely the same kind of grounds, and 'practising the same economy in every thing; because it is quite clear that this would be a diversity without a use, and we have no instance of any such diversity in nature, nor could we at all reconcile it with that wisdom of design and perfection of execution, which run so completely through the whole, and which always appear the more conspicuous the more completely that we examine any one individual part.

The vast number of species of the tanagers, all agreeing in their generic characters, and consequently in their general habits, and all differing specifically and in the details, naturally lead us to expect a corresponding variety in the character of those places over which the birds have to range; and when we turn our attention to the physical condition of South America, we find that it has every diversity of surface, and consequently of surface production, that we can well imagine. On the parallel of the equator, taking it from the lands not of perpetual verdure merely, but of the very excess of perpetual verdure, at and near the place where the Amazon pours its mighty flood into the Atlantic, across Chimborazo to the shores of the Pacific, we have every variety of surface and of climate that can be imagined; and, with the exception of those differences in the length

of the day, and consequent accumulating of the winter into one time of the year, and the summer into the opposite, we have all the varieties which can be met with on the surface of the globe. In many places too we have the greatest seasonal diversities that can occur in a tropical portion of the globe—absolute barrenness from drought at one time, and the most exuberant fertility at another. Then we have a very striking contrast in the country on the two sides of the Andes. The coast country on the east constantly receives the fertilising influence of the trade-wind, and the luxuriance of the vegetation corresponds; while on the west, or Peruvian side, we have a country comparatively parched, until we recede so far inland as to come within the range of the mountain rains.

Such a country must demand a very great diversity of those little birds which, from their numbers in all regions, appear to perform so important a part in the system of Nature; and this seems one of the reasons why the tanagers, which consume the surplus of the smaller fruits, are so very numerous in species, and so varied in their individual habits, at the same time that their general characters are so much the same. But in whatever place they have their principal habitation, the tanagers are chiefly wing birds, moving by short and jerking flights, and feeding on the perch much more frequently than on the ground. On the latter they do not run, as is the case with the thrushes, which, as a family, are placed immediately after them; they hop, or proceed on the ground with a partial use of the wings when they move rapidly. Some of them are found chiefly in the depth of the large forests, but even there the trees are really bushes to them; for they inhabit the tops among the small twigs, and use the wing in passing from one part of the tree to another. Others again live on the confines of the woods, where the bushes in general lose their leaves in the dry season; and the birds which inhabit these must migrate when the produce of the season is exhausted. Those which live most habitually in the woods, are mostly in pairs, or solitary when not in the breeding time; and those that visit the meadows and cultivated fields are more social, and come in flocks. In all these particulars we find that they observe the very same law as the birds of Europe.

In the tropical parts of the continent of South America, the cultivated grounds bear so very small a proportion to those which are still in a state of nature, that they do not materially affect the general character of the country. It is different in a small portion of the coast of Guiana; but even there, the cultivated portion stands to the uncultivated much in the relation of a narrow hem to a wide garment. But in proportion as this cultivated part is small as compared with the country in a state of nature behind, the seasonal visitations of the birds to the cultivated fields are numerous and destructive. It is the same in the countries to the south of the equator; for there the tanagers come from. "They perch in mass and plunder the gardens both of fruits and of the seeds of leguminous vegetables. In the West India islands it is still the same. There, the slopes of the mountains, and all places which are not adapted for the kind of cultivation which is followed as the most profitable, is covered with wood or brush of some kind or other, and very many of the trees composing these woods and bushes, yield berries and other succulent fruits, which feed multitudes of birds, and birds of this genus

or family in an especial manner. But, generally speaking, there are times of the year at which those wild supplies are exhausted; and at these times the birds resort to the plantations in great numbers, and do considerable damage."

In a popular sketch it would be impossible to enter into the details of so very numerous a race of birds as the tanagers; and though our limits would admit of it, it would be only a repetition of matters substantially the same, and varying only in very minute particulars. Those who wish to obtain detailed (museum) accounts of these and the other gaily coloured birds of tropical America, may consult Desmarest's "Natural History of Tanagers, Manikins, and Todies," published at Paris in 1805, in one volume folio. We must content ourselves with merely noticing one or two of each of the subdivisions into which they are divided by Cuvier. There are, 1. Bullfinch tanagers; 2. Grossbeak tanagers; 3. Tanagers properly so called; 4. Oriole tanagers; 5. Cardinal tanagers; and 6. Swelled-billed tanagers.

BULLFINCH TANAGERS. These are also called *Euphous* tanagers, because they are the chief or the only ones that have any noise or notes worthy of being called a song. Their leading characters are: the bill short, and exhibiting, when seen from above, an enlargement at each side of the base; and their tails are also shorter in proportion than those of the other subdivisions. These are among the most compact birds of the genus; and some of them are the most frequent and annoying visitants of the neighbourhood of barns, where they often make the people "pay too much for their whistle."

Organist Tanager (*T. musica*). This species is abundant in many of the West India islands, especially in Haiti, of the natural history of which we had tolerable accounts from the French, before it was expunged

Euphonia Organiste, male.

from the catalogue of civilised countries by coming into the possession of the blacks, morally and intellectually depraved as they were by having been in that state of abominable slavery which has long been the withering blight of so many of the finest portions of the western world. We do not arraign the retributive justice which put that finest of all the West India islands in the possession of these people; but every one must deplore the circumstance of their getting it before they were capable of treating it properly, by which means the garden of the western world has been converted into a tangled and unprofitable wilderness. The bird in question comes near

houses, and though its song cannot be considered a fine one as compared with that of the more choice songsters of the eastern world; it has a good deal of compass and variety. It is a small bird, the total length being about four inches; but as the tail is short, the body is long in proportion. The top of the head, the hind head, and the upper part of the neck are blue, with a black margin on each side; the quills and tail-feathers are black, with rich reflections of blue; the forehead, the rump, and all the under parts of the body are yellow; and the bill and feet are black. The female has the upper parts greenish-ash, and the upper part of the neck pale bluish-grey. It is an active and merry little bird, and shifts its positions on the trees with so much adroitness, that it is caught or killed with considerable difficulty.

Crested Tanager (*T. diademata*). This is a Brazilian species, or, at all events, it is known but as a native of that part of South America. It is a very handsome bird, and, among tanagers, it is one of considerable size, the length being six inches and a half. The upper parts are very brilliant blue, and the under ones the same colour, but considerably darker in the shade; around the base of the bill is deep velvet black; the back part of the head is covered with a fine cape of pure white feathers, in advance of which there is a tuft of silky feathers of a bright flame colour; the quills are black, margined with blue, and tipped with brown; the tail-feathers are also black, bordered with blue, but without any brown on the tips; the bill and feet are greyish-black.

Onglet Tanager (*T. striata*). Buffon gave this species the fanciful name of "Onglet," or ingrooved, from a little groove in the outside of each of the claws, which is not, however, connected with any known habit or peculiar mode of action in the bird. The upper parts are black; the head, the upper part of the hind neck, and the middle and lesser coverts of the wings, azure-blue, but with the roots of the feathers on the latter black; the breast and rump are orange-yellow; the tail-feathers greenish-black; the belly yellow; the bill black above and whitish below. The female is brown on the upper part, with the head and the lesser coverts of the wings mottled and streaked with blue and white; the quills and tail-feathers blackish; the fore neck reddish-brown, and the rest of the under part clear brown; the length, when full-grown, is about seven inches. This is a very handsome and familiar species, abundant in Paraguay, and well known from the proneness which it has to come about gardens and houses; but it is rather a pest to the inhabitants by destroying vast quantities of the seeds, of their leguminous plants, and also of their fruits. The epithet *striata*, which has been adopted as the specific name of this bird, is derived from the blue and white on the female, and not from any markings on the male bird. Indeed, the colours on the males of almost the whole of the genus are as remarkable for being entire, as they are for the brightness of their tints. It is probable that Latham, who applied the name, had seen the female, and described it as a species before he had any knowledge of the male. Other birds have sometimes been very awkwardly named in the same way.

Greenish Tanager (*T. chlorotica*). This is another one, of which the name has apparently been given from the female, and if there is any misapplication, Buffon stands charged with it. The upper parts of the male bird are brilliant violet-black; the forehead,

half the top of the head, the breast, the belly, the flanks, and the under coverts of the tail, deep and brilliant yellow; the quills black, with a white spot at about a third of their length from the base; tail-feathers black, with a white spot on each of the two lateral ones; the bill and feet are black. The female is brown upon these parts, which are black in the male, and greenish where the male is yellow. It is a small species, only four inches in length; and it occurs abundantly in Paraguay and also in Brazil. These are the principal species of the bullfinch tanagers; the most familiar, the most musical, and in some respects the most interesting of the whole. They are birds of gentle and rather social dispositions, and are often kept in cages, the beauty of their plumage making some amends for the inferiority of their music; and they are perhaps the ones that have the nearest resemblance to the females of Europe, though much more gay than these in their plumage; for though our goldfinch is a finely-marked bird, it must yield the palm of brilliance to the tanagers.

GROSS-BEAK TANAGERS. These have the bill conical, thick, arched, as wide as high, and rounded in the culmen of the upper mandible. The species differ in size, but they are, generally speaking, larger birds than the members of the former subdivision. Generally speaking, they have nothing that can be considered as a song, and some of them are remarkable for their silence. Several authors have separated them from the tanagers; but it seems more convenient to retain the genus but with the subdivisions that have been enumerated. The name *saltator*, or leaper, has been given to them, but not very correctly; as all the tanagers have a leaping and not a walking gait, and they are not the only birds that have it; for it is, in fact, a character of a very considerable number of the order, and the one from which it gets the name *Passeres*.

Black and White Tanager (*T. melanoleuca*). This is a Guiana species, and about seven inches in length. The upper parts are black, and there are two stripes of the same colour which extend down the breast, the ground of which, and the rest of the under parts, are pure white: the upper part of the bill is black, and the under part yellow; and the feet are black.

Yellow Tanager (*T. flava*). The upper parts are brownish-yellow; the streak over the eyes and all the under parts bright yellow; the coverts of the wings and the quills brown, with yellow margins; the bill black and the feet brown. It is rather a large species, measuring eight inches in length. Found chiefly in Paraguay.

Lead-coloured Tanager (*T. cærulesca*). Upper parts leaden-grey, with a yellowish streak across the region of the eye; the rump and wing-coverts bluish-black; a black spot at each angle at the gape; the under parts reddish-white; the bill and feet black. It is of the same size as the preceding species, and found in the same part of the country.

Poppy-red Tanager (*T. purpureca*). The upper parts deep flame or fire-red, with some cloudings and reflections of a reddish-brown colour; the quills are brown, bordered with very bright red; and the coverts of the wings reddish-brown, margined with pure red; the under parts purple-red; and the bill and feet black. This is a very showy species, a native of the same country as the two preceding, but smaller in size, the length being seven inches. It must be borne in mind, however, that when these birds are spoken of as inhabiting one place of the warm portion of South America rather than

another, all that is definitely stated is, that they have been seen and described as natives in that particular place; however, notwithstanding that, they may be equally numerous in other places.

Silent Tanager (*T. silentia*). This species is from some part of South America, which is not absolutely ascertained. It is six inches in length; the upper parts are also brown, with a band of bright grey, and one of white from the bill over the eye; the breast white, crossed by a broad band of black, and the rest of the under part white, without any marking of other colour; the bill and feet are black.

Russet-headed Tanager (*T. ruficapilla*). Upper parts bluish-grey; head, nape, and under parts russet-brown; forehead, space between the bill and the eye, and middle of the belly, blackish-russet; the quills and tail-feathers black, clouded with bluish-grey; the bill and feet black; the length seven inches.

Olive-green Tanager (*T. olivacea*). A large species, eight inches in length, and very common in Guiana; but not so annoying on the plantations as the more unusual tanagers; the upper parts are deep olive-green, with a white streak from the gape to the eye, and a black one under it; the chin white; the throat yellow, with a blackish band across; the fore neck and the under parts reddish-yellow, with the exception of the under coverts of the tail, which are russet; the bill and feet are brown.

TANAGERS, properly so called. These have the bill conical, shorter than the head, equal in depth and in breadth; the upper mandible arched and rather pointed.

Archbishop Tanager (*T. archiepiscopus*). This species is very generally distributed, being found both to the east and the west of the Andes, from Brazil to the extremity of Peru; but the height at

Archevêque, male.

which it has been met with on the mountains has not been stated. The upper parts are olive-green; the head, neck, and breast, slate-blue, with violet reflections; the rump and belly grey; the quills and tail-feathers blackish-brown, margined with yellowish-green; the lesser coverts of the wings are bright golden-yellow, and the bill and feet black. The length of the male bird is about seven inches. The female is a little smaller, and has the upper part brownish-grey, with green reflections; and the under part ash-colour, with reflections of violet. The other markings are the same as in the male, only the tints are not so bright.

White-headed Tanager (*T. leucocephala*). Pale blue, with a slight tinge of ash-colour on the upper parts; the quills and tail-feathers black, with bluish borders; the forehead and circle round the eyes are velvet-black; and the top of the head bluish-white, with some reddish feathers next the black; the under parts are black, the bill black, and the feet ash-colour. The length is seven inches, and the species is described as being one of the birds of Paraguay.

The Slave Tanager (*T. palmarum*). This species is also called the palm tanager, from being often found on palm-trees. It is a native of the West India islands, and six inches in length. The upper parts are brown, with olive-green reflections; the wing-coverts, quills, and tail-feathers, are brown, with olive-green borders; and the under parts whitish, with longitudinal spots of brown; the bill and feet are horn colour.

Bishop Tanager (*T. episcopus*) is a native of Guiana, and six inches in length. The male has the upper plumage greyish-blue, with reflections of green and violet; the lower part of the back, the rump, and the under parts, lilac-purple; the lesser coverts of the wings bluish-white, the middle ones violet, and the greater ash-colour; the quills and tail-feathers blackish, with blue borders; the bill and feet black. The female is altogether olive ash-colour, but deeper in the shade on some parts than on others.

Green and Red Tanager (*T. cayana*). This species is found in Guiana, and is four inches and a half in length; the upper parts are green; the top of the head red; the upper neck and rump golden yellow; the sides of the head black; the throat bluish-grey; the under parts mottled with yellow, red, and slate-grey; the quills and tail-feathers bordered with golden green; and the bill and feet blackish. The female is olive-green colour, and yellow with green reflections.

Blue-headed Green Tanager (*T. Linnaei*). This is also a native of Guiana, and a quarter of an inch shorter than the last mentioned. The upper parts are mottled with green and yellow; the wing-coverts and middle tail-feathers are green; the quills and lateral tail-feathers brown, with green borders; the top of the head and the upper part of the neck, both behind and on the sides, violet-blue, with green reflections, and the roots of the feathers blackish-brown; the throat yellow, the middle of the belly golden-yellow, and all the rest of the under part mottled with yellow, green, and reddish-brown; the bill is black on the upper mandible and grey on the under, and the feet are grey. This and the preceding are two exceedingly pretty little birds.

Red-cap Tanager (*T. gularis*). This is a Brazilian species, six inches in length. The upper parts are black; the head and upper part of the throat bright red; the lower part of the throat dull purple; the sides of the neck and the breast pure white; the quills and tail-feathers blackish, and the feet grey.

Seven-coloured Tanager (*T. tatao*). Velvet black on the upper part; head and lesser wing-coverts green; rump orange-yellow; lower neck and greater wing-coverts violet-blue; breast and under parts sea-green; bill and feet black; length six inches. The female has the same distribution of colours as the male, but they are much less brilliant in the tint. It is found in Guiana, and other richly-wooded countries, near the sea or the great rivers.

Blue-headed Tanager (*T. cyanocephala*), is an inhabitant farther into the woods than the last, and

considerably smaller, being only five inches long. It is black on the upper part, with most of the feathers bright green at the tips, which gives it a very rich, though not gaudy appearance. The head and chin are bright turquoise blue; the cheeks and neck red; the lesser coverts black, with orange tips; the quill and tail-feathers brown, with green borders; the under parts green, and the bill and feet black. The female has the head and chin bluish-ash, the cheeks and nape reddish-brown; and the colours of all the other parts much duller than those of the male bird.

Red-head-and-throat Tanager (*T. ruficapella*). This is a Brazilian species, five inches in length. The upper parts are clear olive-green; the head and throat deep red, with a spot of yellow upon each side of the neck, on the rump, and the under tail-coverts; the lower neck and upper part of the breast deep yellow, and the belly paler; the quills brown, with greenish borders; the bill black above and yellow below; and the feet brown.

Three-coloured Tanager (*T. tricolor*). Upper parts blackish brown, with the borders of the quills and tail-feathers bright green; the nape and sides of the neck greenish golden-yellow; the forehead and throat black; the smaller wing-coverts violet-blue; the breast and belly bluish-green; the bill black, and the feet grey. The length about five inches. The female has all the colours paler in the tint than the male. The native country is Brazil.

Varied Tanager (*T. varia*). This is also a Brazilian species, of the same size as the former, but very different in the colours. The upper part is mottled with black and yellow; the head and chin greenish-yellow; the middle of the throat black; the quills and tail-feathers black, with greenish borders; the breast and belly clouded with green and blue; the bill black, and the feet reddish.

Green Tanager (*T. virescens*). This is a North American species. It is olive-green on the upper part; the top of the head blackish; the region of the eye white, with a grey spot between the bill and the eye; the quills and tail-feathers brown, with greenish borders; the coverts deep olive-green; the throat whitish; the under part grey; the under tail-coverts yellowish; and the bill and feet black. It is five inches in length. The reader will not fail to remark that the colours of this species are much less brilliant than those of the ones which are confined to the tropical parts of the continent.

Green Tanager of Brazil (*T. virens*). The upper parts bright green; two spots on the cheek, and also the neck, black; a blue streak from the angle of the gape down the side of the neck; the smaller coverts of the wings very brilliant bluish-green; the middle and larger coverts green; the quills and tail-feathers black, with green borders, the borders with rich reflections of blue; the fore neck yellow; the under part greenish yellow; the bill and feet brown. The total length six inches. A comparison of the colours of this species with the preceding one will show better than any writing on the subject the difference in gaiety of colour between a bird of temperate latitudes and a tropical one.

ORIOLE TANAGERS. These have the bill conical, slightly arched, and notched toward the tip. They are not so numerous as the species of most of the other sections, and the colours of some of them run much upon yellow, which is the chief reason why the name *Oriole*, or golden bird, has been given them.

They have been made a genus under the name *Tachyphonus*, or "swift sounding," probably from the rapidity with which they utter their chirping note; but there is not much use or necessity for the name.

Desmarest's Tanager (*T. Desmaresti*). This is a very small Brazilian species, being only four inches in the total length. The upper parts are mottled with black and yellow; the front and middle of the fore neck black; the top of the head greenish-blue; the sides of the head and all the under parts yellow; and the quills and tail-feathers brown, bordered with yellow; the bill brown, and the feet reddish.

Finch Tanager (*T. fringilloides*). A Brazilian species, five inches in length. Upper parts greyish-ash; the head with two tufts of red feathers; the sides of the neck, the quills, and the tail-feathers, very deep black; the under parts white, and the bill and feet blackish. It is doubtful whether this species should be arranged in the present subdivision, and the same remark may be applied to the next species.

Black Tanager (*T. nigerrima*). A native of Guiana, measuring seven inches in length. The whole plumage is black, with the exception of the lesser coverts of the wings, which are white. The female is red, darker on the upper part than on the under. There are some other species which have been classed in the same genus with these, as separated from the tanagers. In the case of this genus or family of birds there is room for a conflict between the colourists and the structurists, and certainly the colourists have most to say upon the subject, as the birds differ far more in colour than they do in structure.

CARDINAL TANAGERS (so called from their red colours). These have the bill conical, a little vaulted, and with a projecting tooth upon each side. Some of them are found in the southern parts of North America, principally in the valley of the Mississippi, and respecting them we have advantages which we have not in the case of the others, as their habits were observed and described by Wilson. They are birds of passage, and migrate to considerable distances northward in the summer.

The Scarlet Tanager (*T. rubra*). This bird makes its appearance in the middle states of America about May, and finds its way as far to the north as Canada.

Le Tangara du Canada.

It is a bird of the wild woods rather than of the cultivated places, though it visits the orchards, and sometimes builds in them. The usual note of the

bird is short and jarring, and appears to come from a much greater distance than it really does, so that hearing the bird is no very certain guide to a sight of it. Occasionally, however, the male utters a more mellow note, though even that is not properly a song. The food of the bird is hornets, wasps, wild bees, and other large insects, and toward the end of the season the berries of some of the *vacciniums*, and other small wild fruits. Wilson puts in a plea for the bird in the following passage:—"Among all the birds that inhabit our woods, there is none that strikes the eye of a stranger, or even of a native, with so much brilliancy as this. Seen among the green leaves, with the light falling strongly on his plumage, he really appears beautiful. If he has little melody in his notes, he has nothing in them to disgust. His manners are modest, easy, and inoffensive. He commits no depredations on the property of the husbandman, but rather benefits him, by the daily destruction in spring of many noxious insects; and, when winter approaches, he is no plundering dependent, but seeks, in a distant country, for that sustenance which the severity of the season denies to his industry in this. He is a striking ornament to our rural scenery, and none of the meanest of our rural songsters. Such being the true traits of his character, we shall always with pleasure welcome this beautiful inoffensive stranger to our orchards, groves, and forests."

The nest is built about the middle of May. It is placed on a horizontal branch of a tree, simple in its structure, being composed of dry vegetable fibres, without any elaborate lining with softer matters. The eggs are three in number, of a dull blue colour, spotted with purple brown. The birds have only one brood during their sojourn in the United States; but, as they depart as early as August, it is not unlikely that they may have an autumnal brood in the more tropical country to which they retire.

The male, when arrived at his full size and colour, is six inches and a half in length, and ten and a half in the stretch of the wings, being much better winged than those tropical species which are not migratory. The clothing plumage is of a most brilliant scarlet, and the quills and tail-feathers black, but sometimes with a little white on the tips; the margins of the inner webs of the quills are also generally white or whitish; the tail is much forked, which agrees with the habit of the bird in snatching insects on the wing; the bill is large and strong, and, like that of the rest of the section, tumid; it is of a yellowish horn colour, but subject to changes with the seasons. The moult commences about the 1st of August, the scarlet feathers being partially displaced by greenish-yellow ones, which gives the bird a mottled appearance, and the whole change of the body-plumage has not taken place when the bird departs for the south. Where they retire, and when they regain their scarlet livery, are not known, but they have it perfect when they return to the north. This, however, is true of the mature birds only; for the young of the preceding year have some green mottlings when they first come, though these soon disappear, and they shine out in all the splendour of their parents.

The manners of these birds are fully as attractive as their plumage, gay and beautiful as that is. Both birds are very vigilant in watching and protecting the nest, and also in feeding the young, even after they are considerably grown. The following anecdote, given by Wilson, is too characteristic for being omitted in noticing so numerous a genus of birds, of

the manners of by far the majority of which we know absolutely nothing:—"Passing through an orchard one evening, I caught one of these young birds that had but lately left the nest. I carried it with me about half a mile, to show it to my friend, Mr. William Bertram; and, having procured a cage, hung it up on one of the large pine trees in the botanic garden within a few feet of the nest of an orchard oriole which contained young, hoping that the charity or tenderness of the orioles would induce them to supply the cravings of the stranger. But charity with them, as with too many of the human race, began and ended at home. The poor orphan was altogether neglected, notwithstanding its plaintive cries; and, as it refused to be fed by me, I was about to return it back to the place where I found it, when, towards the afternoon, a scarlet tanager, no doubt its own parent, was seen fluttering round the cage, endeavouring to get in. Finding this impracticable, he flew off, and soon returned with food in his bill, and he continued to feed it till after sunset, taking up his lodgings on the higher branches of the same tree. In the morning, almost as soon as day broke, he was again seen most actively engaged in the same affectionate manner; and, notwithstanding the insolence of the orioles, continued his benevolent offices the whole day, roosting at night as before. On the third or fourth day he appeared extremely solicitous for the liberation of his charge, using every expression of distressful anxiety, and every call and invitation that nature had put in his power, for it to come out. This was too much for the feelings of my venerable friend; he procured a ladder, and, mounting to the spot where the bird was suspended, he opened the cage, took out the prisoner, and restored him to liberty and to his parent, who, with notes of great exultation, accompanied his flight to the woods."

Such is the tale of most perfect and most graphic truth, told by one of nature's own ornithologists; and the tanager, and Wilson and Bertram, must share the admiration of every reader who can feel. It would not be right, however, to suppress Wilson's reflections—"The happiness of my good friend was scarcely less complete, and showed itself in his benevolent countenance, and I could not help saying to myself—If such sweet sensations can be derived from a simple circumstance of this kind, how exquisite, how unspeakably rapturous, must the delight of those individuals have been who saved their fellow-beings from death, chains, and imprisonment, and restored them to the arms of their friends and relations! Surely, in such godlike actions, virtue is its own most abundant reward!" Where, among the romances of human life, shall we find expressions so pure and warm from the heart as these; and who, that sees its aspirations rise to this height, would refrain from being an ornithologist—living, as one of nature's brotherhood, with the lovely and lively tenants of the wood?

Summer Red Tanager (T. æstiva). This species is found in nearly the same places, and at the same time, as the preceding, and either of them might be characterised by the epithet *red* or the epithet *summer*; for they are both red birds and both summer birds. The two are, however, at once distinguished from each other, and the present is by no means so brilliant a bird.

The male is not scarlet, but rich vermilion-red, most brilliant on the under parts of the body, and the inner margins and tips of the quills are reddish-

brown; the bill is very large, and inflected with a prominence on the upper mandible, and it is of a yellowish horn-colour in its whole length; the tarsi and toes are light-purplish blue; the eye is large, and the iris hazel. It is rather larger, and also better winged, than the scarlet tanager, being seven and a half inches long, and a foot in the stretch of the wings. The female is rather smaller, and different in the colours, the upper part being brownish yellow-olive, the under part orange-yellow, and the tips and inner webs of the quills brown. The naked parts are the same colour as those of the male. The nest is in the woods, on a lateral branch of a tree, or on an evergreen, and rarely more than ten or twelve feet above the surface of the ground. Like that of the scarlet species, it is composed entirely of vegetable fibres, but a little more elaborately finished than the other. The eggs are three in number, and of a black colour. The nesting-time is in May and June; and in August the birds depart from the United States for the south. Whether they have or have not an autumnal brood on their southern retreat is a point which has not been ascertained.

The young differ much in colour from the full-grown birds, and these are also very differently coloured before or after the autumnal moult, or rather, perhaps, during the progress of that moult. The young are at first of a yellowish-olive on the upper part, something resembling the under part of the native female. They are partially mottled when they make their first appearance in the south, but acquire their full tint in the spring of that year. It is probable that those tanagers which visit North America in the summer return to Mexico, or to the narrow but thickly-wooded country near the Isthmus, in the winter, and do not pass either into the West India islands or into South America; at least, none of the species which are described as South American agree exactly with these in their characters. The South American ones have the tails nearly square, or rounded, or wedge-shaped, while those North American ones have them forked. This causes a difference in the style of flight, which has probably reference both to the feeding and the migration. They appear to feed more upon the wing, and more upon winged insects, than the South American birds, and they are certainly much more migratory in their habits, so that they are perhaps better entitled to be considered a separate genus than any of the other sections.

There is a beautiful provision of nature in the difference of colour between the females and young of these birds, and the old males, in the season of rearing the brood. The old males, in their red livery, are among the most conspicuous objects which can be placed in the green leaves of a forest. Their colour is the complicated colour of the leaves, and thus they mutually render each other more conspicuous. The colour of the females and young, again, is nearly that of the leaves themselves, and thus it is with difficulty that any enemy can see them while quiet, or in the nest. Now, in the hatching time, the female remains remarkably close and still, while, if any cause of alarm appears, the male is all bustle and activity, and can scarcely fail in drawing upon himself the attention of the enemy, at the same time that he is so alert that few enemies can harm him. This is equally true of the scarlet species and the darker red one. The green colour which comes upon the male at the time of the moult seems to be

equally conducive to safety. Birds, when moulting, are weak, and unable to escape danger, or defend themselves with the same vigour as when they are in full plumage. Both species moult early, while the snakes, which are the great enemies of the smaller forest birds of North America, are still in their summer activity, and the green colour renders the male less easily seen by them at the time when it is not necessary that he should exhibit himself conspicuously for the purpose of drawing away their attention from the female and the nest. There is no doubt that all colours, and all changes of colour, in birds are conducive, in some way or other, to safety, though the subject is so extended and so intricate that we have very little knowledge of it. That it is the male bird which, in all cases where there is a nuptial change, acquires the showy and attractive plumage, is of itself sufficient to establish the truth of the general principle; and when once this is established, every observed fact becomes an addition to our knowledge.

The haunts of the summer red bird are not exactly the same as those of the scarlet tanager. It keeps more to the sandy flats which are covered with wood, and does not migrate so far to the north. Hence it is most abundant in the southern states near the coast, where much of the country is of that character. Its food, though analogous to that of the other species, is not quite the same. Coleoptera, and various wingless insects, are very numerous near the country woods of those places to which the birds resort in greatest numbers during the summer; and of course the birds feed much upon these, though they do not refuse naked-winged insects when these come in their way. The tanagers, small birds as they are, do not appear to feed on the very smallest of the insect tribes. In the early part of the season, their food, like that of the scarlet species, appears to be almost exclusively animal; but when the wild berries on the low bushes on the margins of the swamps are ripe, they live in a great measure upon these. The female has a feeble and chattering kind of note without the least music in it; but, though not a regular songster, the male has a clear and trifling sort of whistle. When the beetles fly on the wing, which is the general habit of many of the earth and aquatic ones at a certain season, the red tanagers hawk for them on the wing in the open places, and catch them with no inconsiderable adroitness. Altogether, they are birds of no little interest.

Louisiana Tanager (T. ludoviciana). This species inhabits farther to the west than any of those that have been mentioned, and our knowledge of it is far more limited. It is found to the west of the Mississippi only, and rather toward the mountains than in the low and damp plains near the river. According to the accounts we have of it, which are not, however, very perfect, it appears to frequent more arid and open places than either of the other two species of the same latitudes. We have thus each of these three migrant tanagers upon a different locality during the time they are in the United States; the dark red one nearest the sea on the low sandy grounds, which grounds are, however, covered with cedar and other trees wherever there is a sufficiency of moisture. The trees in such places are very much injured by beetles and other insects; and there is no doubt that the tanagers assist considerably in protecting them. The scarlet tanagers are more in the rich woods near the great rivers, where there is no doubt that they

also, from their numbers and their activity, perform far from an unimportant part, both in wild nature and cultivated—the latter because they are birds of more habitable places than the former one. The Louisiana tanagers, again, are found more upon the dry prairies between the western branches of the Mississippi, in places where there are not continuous forests or many tall trees, but abundance of bushes, which afford them cover, and furnish them with insects in the summer, and supply abundance of berries in the advanced part of the season. The changes of plumage in this one are not very perfectly known. The wings, the tail, and principal part of the back are stated as being black; the coverts of the wings being mottled with black and yellow. It is generally supposed that the males of these birds are, like the other species which migrate into North America, red in the summer; but the fact wants to be more fully cleared up. Their habits on the breeding grounds are not quite the same. Both the others build in trees, generally in thick and close trees, though not at any great elevation; but these western ones build in low bushes, and even in the tufts of tall herbage.

The common opinion is, that both this western species and the scarlet one pass into Mexico in the winter, and it is by no means unlikely. There has indeed been a Mexican tanager described, very much resembling the scarlet one, which comes into the United States; that is to say, it is of the same size and colour, and has the tail forked; but there is no information as to whether it is or is not a resident bird, or at what time of the year it appears in Mexico. It was not the policy of the Spaniards, while they had possession of the country, to let us know any thing about even its natural history; and since the Spanish domination ceased, the state of things, in this respect, has not become better. At the time when Central and South America were first subjected to the iron yoke of Spain, the Mexicans were much lower in the scale of human nature than the Peruvians, and they again, in so far at least as spirit and enterprise were concerned, to the people farther to the south; and whether that difference be mainly owing to climatal causes or not, the same difference remains to the present day. This is proved by the state of the natural history of those places; for we have D'Azara's very valuable information respecting the south, while of Mexico we have nothing of value. We must, however, briefly notice the remaining section of the tanagers.

SWELLED-BILLED TANAGERS (Ramphocelus). These have the bill conical, with the sides of the lower mandible swelling out toward the base. The species are not numerous, and one which has been described as the Canada tanager appears to be nothing else than the scarlet tanager, which has been already described as a summer migrant in the United States.

Jacapa Tanager (T. purpureus). This is the characteristic bird of the section, and the peculiarity is in the bill. Toward the tip that does not differ much from the bills of the rest of the family; and the upper mandible and distal portion of the lower one are black; toward the base the sides of the lower mandible are very tumid, and when the bird is alive, those portions are brilliant silvery-white, which, however, like the bloom on all the naked parts of birds, speedily fades after death. The male bird has the upper plumage black, with the exception of the head, throat, and breast, which are purple-red; the feet are black; the total length six inches. The female wants

the silvery-white on the lower mandible, and the colours are brown and dull purple. The birds are found in the tropical parts of South America.

Scarlet Tanager of Mexico (T. rubra). There are some doubts whether this may not be the same bird as the scarlet tanager of the United States, though the bill is not of the same colour. At all events they resemble each other so much in other respects, that a popular description of this one would be little else than repeating that of the other.

We shall not farther extend the list of these very abundant and beautiful birds; and we have given an outline of the colouring of so many of them, merely to show what endless variety Nature can produce in this way, with almost equal beauty throughout the whole series. Whatever happens to be the particular tints and markings of any of these birds, there is a delicacy in the colour which, those who have not seen tropical birds in the living state cannot readily understand. Their manners, too, are gentle in all the species, though at the same time lively. They are indeed, generally speaking, birds of great activity; and though their broods are not numerous, they are attentive parents, and have their paternal duties to perform twice in the year. They give a great deal of liveliness to the borders of the forests, in those situations where the true climbers, and other characteristic birds of the depth of the forest shade, rarely come. The characters of those forests can hardly be described; for there is every kind of country within a short distance, and, being in most places completely in a state of nature, each place has its characteristic inhabitant—exactly the one which is fitted to its physical state, and its seasonal condition at the time that it is seen. Upon the margin of the arid waste, or that place which is apart in the rains, and barren as a trodden path in the drought, we have one of these birds on the very first bush that we come to; and, as is the case in our own country, that one usually has a little song to welcome one to the study of the mighty museum of living Nature, which lies hidden in the wide and deep shade of the all but interminable forest. Years, centuries, must however roll over our heads, or equal periods of oblivion over the generation which now inhabits the earth, before the volume of this mighty book of Nature shall be opened even to the most zealous and able inquirer. While this is the case, there need no man be under the slightest apprehension that the pleasure of discovering either the facts or the laws of Nature shall ever have an end.

TAPIR (Tapirus). A genus of pachydermatous mammalia, of which there are two living species found at places of the globe which are nearly the antipodes of each other—South America and the Oriental Isles. This is not the only point in which these two regions agree in their natural history, and differ from all other places. South America is, indeed, an extensive country, with a very varied surface, and therefore we cannot speak of the whole of it as being comparable with the isles of the East, which being small, as compared with it, in their individual, and even their collective extent, have their natural character much more uniform. But the shores of South America, upon which the trade-wind beats, and the valleys of the rivers as far inland as the influence of the trade-wind extends (which, under the equator, where the continent is broadest, is nearly three-fourths of it, including Brazil and the greater part of the valley of the Amazon), has very

much the character of the eastern islands, and also of the Malay peninsula—in short, of the whole of that portion of Asia which is under the influence of the trade-wind of the Pacific. The east side of Africa is not of the same character, because the ocean to the east of it is cut off from the Pacific by Australia, and converted into a monsoon sea by the alternating action upon each other of the sea in the south and the land in the north. This is the true reason of the anomaly which we always meet with from Africa when we compare the natural history, and more especially the zoology, of the tropical parts of the earth; and it is necessary that we should bear them in mind, if we are to study the general relation of that natural history in a profitable manner.

Those regions which enjoy the continual action of the trade-winds appear to have a power of preservation and endurance in them which we do not meet with in places which are less under the controul of any air current from the sea. Their forests do not appear to wax old like the forests of other places, but to be the same day after day and century after century; and thus we may be prepared to meet with, in them, both plants and animals which have perished from the other parts of the earth, or, if not animals of the same genus or species with the lost ones of other regions, yet animals of the same order.

In the article MAMMALIA, to which we beg to refer the reader, there will be found some remarks on the pachydermata, and, among others, that this order of animals is little else than a collection of fragments, having much less similarity to each other than the animals of almost any other order. If we except the phoca genus, which have but little in common with the other pachydermata, we find that all the rest belong to a remote state of the globe—a state in which it is, or must have been, covered by an exuberance of coarse vegetation. It is true that some are fitted for eating the roots and seeds or fruits of that vegetation, as, for instance, the hog; while others can almost subsist by gnawing the succulent twigs which grow by the banks of the rivers, as is the case with the hippopotamus; but in the portion of the system which lies between them we find that the succession is constantly broken, and that we are in want of one or more races to make out the connexion, so that we might understand how the animals could work together with anything like the same harmony which strikes us at once in other parts of the system.

It is the vegetable feeders which are of the most value to us in that part of natural history, by which we seek to trace the relation of the kingdoms of nature to each other, and the whole to the physical condition of the globe. If we take the ruminantia, for instance, we can easily trace them, in a very regular and obvious series, from the buffalo on the swampy plain, by the sea, or the broad river, to some light and bounding animal on the mountain-top. So tracing them, we can see their perfect adaptation to the state of things as now existing. But, when we have recourse to the pachydermata, we can make no such general allocation to all the principal varieties of surface as we now find them. We have stated that the phoca family are an anomaly among the pachydermata, and could not very easily be brought into any series with the rest, even if we were to suppose that as many fossil races should be discovered as would fill up the other blanks. The camel family stand in the same anomalous position

among the ruminants; and it is not a little curious that these two anomalous families, of different orders, should have their native localities near, or somewhat resembling, each other, and that they should be used for nearly similar purposes by man—should be the “beasts of burden” by way of eminence. Such, however, is the fact; and it is a fact, the investigation of which is far from being unimportant, only it is inconsistent with our present object, and incompatible with our limits.

The tapir is a genus which stands at a break in the series, and with it the pachydermata, if we begin them with the elephant, may be said to terminate. It may be taken up from the rhinoceros, with which the tapirs have more characters in common than with any of the rest. But even here there is a wide difference, and some lost genera come in between, as well as the living genus *Hyrax*, which is very different in its habitat. The last ones appear to approach more nearly both to the rhinoceros and the tapir.

One of the selat ones is the *Palæotherium*, which appears to have been at one time very plentiful in Europe, as there are about a dozen fossil species in the Paris basin only. Some of these are equal in size—that is, from their skeletons they must have equalled in size the rhinoceros of the present day, while others could not have been larger than small sheep. They occur in great numbers in the calcareous deposits, and their accompaniments being fresh-water shells, and other aquatic remains obviously not marine, show that they must have inhabited the shores of lakes, or other banks of slowly-flowing rivers. They had the teeth very like those of the tapirs, and, like them, they must have had the muzzle drawn out into a fleshy and flexible snout, as the places for the insertion of the muscles for the moving of such a snout are quite obvious on the bones. They had a toe fewer on each fore-foot than the tapirs, and differed from them in many minor particulars; so that, though their haunts and habits must have been similar, they could not have been exactly the same. The other last genus, *Lophiodon*, had the teeth different, formed into transverse elevations in the lower jaws, which is evidence of these having to bruise more stubborn food than the preceding species.

Our present business, however, is with the tapirs, of which, as of very many of the pachydermata, there are remains of fossil species in places where there have been no living native ones within the period of recorded history. The generic characters of the tapirs are as follow: six incisive teeth, two canines, and fourteen grinders, in each jaw, the latter equal in number above and below; the intermediate incisive teeth smaller than the lateral ones, and thus giving them something the appearance of additional canines; the canines of moderate size, with a space between them and the cheek-teeth, the latter with two transverse ridges on their crowns; the jaws are long, and the mouth is thus simply furnished with all the three kinds of teeth, which indicates that the animal must have corresponding labour in eating; the mouth is a ragged, or what we would call an “ugly mouth,” capable of bruising very hard and tough substances; there is, however, nothing of a murderous or carnivorous character about it; but the three kinds of teeth complete, always in the absence of any thing carnivorous, indicate a miscellaneous feeder, of which the common hog is a familiar instance; the nose of

the tapir is elongated, forming a moveable proboscis, but not a prehensile one, like that of the elephant, and proportionally much smaller than in that animal; the eyes, as in most of the order, and in all the long-snouted ones, are very small, and the ears of moderate length, erect, and moveable; the fore feet have four toes each, and the hind feet three, with a small hoof on the extremity of each toe, the hoofs rather pointed, and divergent, but not in the least resembling claws; the tail is very short, and the hind part of the body droops much to its insertion; the skin is very thick and strong, forming slight folds or wrinkles on the flanks and some of the parts, and it is thinly covered with very short hair, which lies flat, and shows the whole form of the animal; that form is heavy, and the expression is dull and stupid, and indicative of nothing that can be called spirit. It partakes a little of the horse, of the hog, and of the rhinoceros, but it has not much likeness to any of them. The females agree with those of the horse and the rhinoceros, in having two mammæ situated in the groin, but no neutral ones like the hog. There are considerable differences between the two species, as we might be prepared to expect from their habitats being so wide asunder.

AMERICAN TAPIR (*T. Americanus*). When full grown, this species is about the size of an ordinary donkey, and, small as it is, it is the largest of the land mammalia of the rich and humid places of South America. The head is very thick and clumsy, elevated at the occiput, and bearing in the profile some slight resemblance to that of a hog, but without any of the energy which is characteristic of that animal in the wild state, or of the intelligence which it has when domesticated and well attended to. The eyes are very small, and the trunk of the nose is much smaller than that of the hog, and its motion is more feeble, and of a different character. The cartilaginous point only of the hog's snout has motion on the peculiar bone, but that of the tapir can move a little both downwards and laterally. It has not action enough for actually seizing any substance, but it may assist the animal in opening up a passage among the thick and tangled vegetation. It is not used in rooting in the ground, and it is not adapted for it. It has no cartilaginous termination, but is almost entirely composed of muscles. The body of the animal is thick and clumsy; the tail is very short and straight, ending abruptly, as if it were a stump; the colour varies from blackish-brown to brown, with a shade of dull fawn colour. The covering of the body, as was said, is smooth, but the male has the trace of a mane along the ridge of the neck.

This tapir is pretty generally distributed over the rich humid and shady parts of tropical America, but it is nowhere very abundant; and it is so dull and unsocial in its manners, that it is rarely seen even in those places where it occurs most frequently. It is not fond of the company of its own species, like the greater number of the pachydermata, never more than a pair being seen together, and rarely more than a single individual. It is very much of a nocturnal, or, at all events, of a twilight animal, in its feeding, and dozes away the greater part of the day, sleeping in the shade of the close sprays near the streams, from which habit, and the obscure colour of its body, one may pass close to it without being aware that it is there. In the night it comes abroad, and feeds on wild fruits and other pulpy and succulent vegetables, if it can find them. If they are not to be had, it is

not very particular as to the choice of a meal, for it can gnaw twigs, or eat carrion; and it is said at times to swallow the same sort of fat clay which report mentions as part of the seasonal food of some of the Indian tribes of the Orinoco, and some other damp and wooded places. Like many of the order, it is very tenacious of life, and affords another proof of the general law, that the more passive and sluggish that life is in any animal, it is extinguished with the greater difficulty. It is some time before even the most serious wound takes effect upon it; and D'Azzara mentions that he has seen one continue to run for some time after two musket-balls had passed through its heart. It is fond of the water, and swims well with a leaping motion something like that of a pig; but it does not dive or repose in the water like the hippopotamus. The water is usually its retreat, however, when it is wounded, and probably also its last resource against the attacks of the jaguar. The Indians, who are by no means particular in their appetite, hunt it with avidity, and readily eat its flesh; but it is not relished by the Europeans or their descendants. The Indians shoot it with their poisoned weapons, or kill it with those of their usual warfare, and one is esteemed a prize for a family. The Europeans also sometimes hunt it, using dogs to drive it from its cover; but this is done from sport, or from the idea that it injures their plantations, which it is very apt to do to those that lie near the woods.

When attacked it offers but little active resistance, and never bites, though its mouth is tolerably well adapted for that purpose. It utters a complaining cry, which is a querulous kind of hiss, and not in the least resembling the squeak of a pig in affliction. Its first attempt is to escape by creeping into the brushwood, which it does with much ease and speed considering its voluminous size. This is also understood to be its first and readiest resource in case of an attack from its feline foe, as it is much more dexterous in threading the brake than the jaguar. Its head is indeed remarkably well adapted for boring through tangled places, being in the form of a conical wedge, and so thick toward the posterior part, that wherever it opens a way, the rest of the body can pass, thick and clumsy as that is. Its only means of active resistance is said to be kicking with the heels, in which it is represented as being rather dexterous, and to which mode of defence it has recourse, when it cannot force its way into the place where it has made the attempt. When hard pressed by the dogs, it will also seize them by the back with its rough mouth, and shake them till the skin is lacerated or torn off, but it is unable to give them a regularly wounding bite. The females bring forth their young, which is generally only a single one, in the month of November, which answers to the May of our year; but the male lives apart, and takes no interest in the progeny; and even the female is said to have but very little affection for her young.

The tapir is thus one of the most passive of the mammalia, and one which stands low in the scale, both in sensation and in action. Its sight is, in all probability, not very keen, as that is a sense of which it does not often make use. Its skin is also not well adapted for being a general organ of touch; and the miscellaneous nature of its food prevents us from supposing that it can have much taste. Their ears and nose being the organs of sense that are most developed, they most likely depend most on smelling

for their food, and on hearing to keep out of the way of danger.

Their passive nature renders them easily tamed, if taming it can be called in animals which cannot be made to harm any thing. We are not aware that they are in any instance bred in confinement, as they do not possess any obvious property that makes them worth breeding; but when taken young, they go about the house inoffensive to all other animals, never attempting to escape, and eating indifferently of any kind of food, animal or vegetable, of which, however, they require a very considerable quantity. We omitted, in noticing the structure, to state that the head and neck of the tapir, as far as the shoulders, are fortified with a sort of shield, by means of which it can raise the bushes out of its way without sustaining so much injury as an animal having only ordinary skin. On the head this shield consists of a thickening of the outer table of the cranial bones; but on the neck and shoulders it consists of a very thick and indurated skin. The full-grown animals, though they vary a little in the shade of their colour, have it entire without any markings; but the young ones are dappled over something in the same manner as fawns, or rather perhaps spotted hogs. Taking it altogether, there are not many animals more destitute of attractive qualities than the American tapir.

THE MALAY TAPIR (*T. Indicus*), is a much more recent addition to the animals known to Europeans than the tapir of tropical America, and it differs in many particulars. It is not met with in continental India, or we believe in Ceylon, but only in the Malay islands and peninsula, though in how many of them is not known. It is altogether a much more massive animal than the American tapir; thicker in the body, shorter and thicker in the head, and with the legs much shorter and stouter, and the feet broader; but the number of toes and hoofs is the same as in the other, and the character of the mouth differs little if any thing. The feet are adapted for walking on softer ground than those of the American tapir, and the animal appears to be more aquatic in its habits. The animal is perhaps a little heavier than the American, but it is not quite so long. The flexible part of the snout is a little larger, in proportion, being seven or eight inches; but the bones which support its face are shorter. The outline of the profile is also more convex, and the snout is, in its integument, a little more like the proboscis of the elephant, though it is not actually prehensile, otherwise than by pressing against the under lip; the eyes are small, and the ears rounded, with white hair around their margins; the skin is very thick and strong, with very little hair, what there is, is very short, and no vestige of a mane on the neck or shoulders; the colour from a little behind the fore legs and shoulders, quite round the body as far back as the groin, and down the rump to the root of the tail, is of a uniform sandy white in the mature animal, and the rest of the body and the legs are black. This marking gives it a very odd appearance, as if it were a jet black animal with a dull white cloth wrapped round its body, from near the fore legs to the rump. This white patch is not, however, constant in its shape and size; for in some specimens the middle of the belly is black; and it is by no means improbable that there may be still greater differences of colours than these; for animals which have their colour broken into large patches, as these have, are seldom constant either in the size or the shape of the patches. The young are much

more varied in the colour. They are represented as being beautifully mottled with black, white, brown and fawn-colour; the stripes and spots of fawn being upon the upper part of the body, and the white ones toward the under part. The colour changes when it is about half a year old.

It appears that, though a recent addition to our zoological catalogues, it is far from rare in many parts of the Malay country, both in the islands and peninsula. The tribes of different parts, both of the coast country and the interior, have different names for it, which is one pretty strong proof of its being a native animal in them all. It is probable that Europeans resorting to these islands have been aware of its existence for a long time; but that a double mistake was committed respecting it. It was considered as a hippopotamus, and thus that animal, of which there is no living instance but in Africa, was transferred to the Malay country; and it was confidently said, that there was no species of tapir but the American one. The researches conducted by Sir Stamford Raffles, and also by the French naturalists Diard and Douceville, brought to light many of the singular productions of those interesting countries, and make us wish, for the sake of natural science, as well as for the arts and the advantage of those places themselves, that they had continued a little longer.

The full-grown ones in those parts of the country which are most favourable for them are large animals, as much as eight feet in total length, and more than six feet in the circumference of the body. But as they are animals of concealment during the day, and also of retired places; and as, under the former system of treating the natives of these countries, it was by no means safe to make excursions to any distance from the fort or factory, there were not the means, even if there had been the desire, of knowing much about the natural history.

A living specimen, which Sir Stamford Raffles sent from Bencoolen to Bengal, while it was yet young, showed the same inoffensive disposition as the American one. It was taken to Barrackpore, where a collection of animals is or used to be kept; and it went about quite at its ease, being fond of the water, and often entering into the ponds and tanks, in which, contrary to what is stated of the American one, it walked on the bottom under the water, and showed little or no disposition to swim. The length of the movable snout fits it for a habit of this kind, as it can breathe at a much greater depth than a short-nosed animal; and the structure of its feet, and the whole air of its body, are much more aquatic than those of the American. Of its breeding time, or the period of its gestation, or indeed of any of its habits in its native haunts, we know little or nothing. It seems to be a law among the pachydermata, and it is rather a curious one, that those genera which have many mammæ on the belly in the females, and numerous litters at a time, are also animals of very short gestation; while those which have but two mammæ in the groin, and produce but one or rarely two at a birth, have the period of gestation much longer. This makes them doubtless inferior to the others in productiveness; but there is a compensation in nature, the animals are in themselves much more hardy and long lived; and their own strength, and the places which they inhabit, conspire in making them much more secure from enemies. In a state of nature the two may be found at no very great distance from each other, but they are never exactly on the same kind of

ground; and as generally inhabiting every part of the world, they evidently belong to very different states of it. The tapirs belong to those with only two mammæ, and they occupy nearly the same kind of ground; and hence we may conclude, that the countries where they are now found only in the fossil state were very different in their physical state from what they are now.

Two fossil tapirs have been mentioned, one as occurring in France, and the other in North America. Of the remains of the French one, there can be no doubt; but the American is much more questionable.

The French one is the gigantic tapir (*T. giganteus*), and it well merits the name; for the bones show that it is well entitled to the epithet, as they indicate a size and strength not inferior to those of the rhinoceros, or even of the elephant itself. Their horns are found in the alluvial deposits, at least judging from the teeth, which are almost the only bones that have been found; but such is the perfection to which comparative anatomy has been brought, that the size and the leading characters of an animal may be tolerably made out from a single bone.

The supposed American species is a much smaller animal, though larger than the bony tapir of that continent. It has been called *T. mastodontoides*, from the resemblance of its remains to those of the mastodons, especially those of the large one, which are found in the same places of North America; and it is highly probable that they have not belonged to a tapir at all, but to a mastodon, which resembles the elephant more in all those characters that can be made out; so that Europe is in the mean time the only part of the world in which we can distinctly say there are the fossil bones of a tapir.

TARANTULA, or TARENTULA, the ordinary name given to many large species of spiders, including those of the genus *Mygale*, but more strictly applied to a species of *Lycosa*, found in the south of Italy, and especially in the neighbourhood of Tarentum in that country, whence it has obtained its ordinary name, and which has become famous not only on account of the supposed venomous effects of its bite, which are stated to have been followed by death or tarentismus, but also from the supposition that music and dancing were the only remedies against this insect's bite. The *Tarantula* belongs to the division of the cucular or mining *Lycosæ*, which inhabit subterraneous intrenchments, which they construct for themselves. The most elaborate account which we possess of this spider is given by M. Dufour in the *Annales des Sciences Naturelles* for 1835, and which has been translated in the new series of the *Magazine of Natural History*. M. Dufour had studied its habits in different parts of Spain, and is convinced that the species which he investigated is the true *Tarantula* of the ancients, of all authors who have written upon tarentismus, and of Baglivi, Linnæus, Fabricius, &c. It is on the upper side of the body of a grey colour, varying to blackish or clay-coloured, with a paler margin to the body; the cephalothorax more or less clouded; the mandibles black, with the base in front greyish; the back of the abdomen with two or three somewhat arrow-headed marks and transverse posterior fascia of black; beneath it is black; the belly velvety-black, with the margins and anus broadly ochraceous; the trochanters and base of the femora and tibiæ having two black spots. It varies in its length from ten to fourteen lines.

The following particulars relative to the habits of this insect are concisely abstracted from M. Dufour's Memoir above quoted. It is in exposed dry barren places that the *Tarantula* constructs its burrows in the earth, and which are an inch in diameter and a foot in depth. For securing both a safe retreat and a place of ambuscade, the *Tarantula* has the instinct to construct its passage at first in a vertical direction; but at four or five inches from the surface it turns in an obtuse angle, forms a horizontal bend, and then reassumes the perpendicular. It is at the commencement of this bend that the *Tarantula* establishes himself as a vigilant sentinel, and never for a moment loses sight of the entrance to his abode; and it was there that at the time when M. Dufour discovered him, he was betrayed by his eyes glittering like diamonds, and rendered bright like those of a cat by the darkness. The ordinary entrance to the burrow is surmounted by a funnel somewhat similar to that formed by some of the sand-wasps (*Odynerus*), composed of fragments of dried wood, united by a little clay, and lined within with a tissue formed of the threads of the *Lycosa*, and which is continued through the whole interior. It is easy to conceive how useful this skilfully fabricated drapery must be both in preventing the crumbling in of the earth, or any such accident, and also in assisting the *Tarantula* in scaling its fortress. The funnel, moreover, protects the burrow from inundations, and fortifies it against falling bodies, which, swept by the wind, would be likely to close it up; it also serves as an ambush, by offering to flies and other insects upon which the *Tarantula* feeds an enticing resting-place.

M. Dufour then details the various manœuvres he was compelled to employ, in order to obtain specimens of the spider, by digging or enticing them out of their holes; from this detail it appears that the spider is both wary and courageous whilst in his retreat, but confused when found out of it. The Apulian peasants adopt another plan for capturing the *Tarantula*; according to Baglivi, these country people make a buzzing noise like the humming of a bee at the mouth of the hole, which is mistaken by the spider for its prey, in pursuit of which it comes out of its hole, and is immediately caught. Notwithstanding the obnoxious appearance of this creature, it is capable of being tamed; and M. Dufour gives us the history of a specimen which became so contented and tame, that it would come out of its hole and eat from his fingers the fly that was brought for it.

According to the old authorities, the bite of the *Tarantula* occasioned an inflammation in the part, which in a few hours brought on sickness, difficulty in breathing, and universal faintness. The person afterwards was stated to be affected with delirium, and sometimes to be seized with a deep melancholy, the symptoms returning annually in some cases for several years, and afterwards terminating in death. According to others, the symptoms produced by the poison were similar to those of malignant fever; whilst by others the skin exhibited only a few erysipelatous spots. Music, it was pretended, was the only remedy. A musician was brought, who tried a variety of airs, till at last he hit upon one that urged the patient to dance, the violence of which exercise produced a proportional agitation of the vital spirits, attended with a consequent degree of perspiration; the certain consequence of which was a cure. Such are the circumstances which have been generally

related and long credited regarding the bite of this animal. Kircherus in his *Musurgia* gives a very particular account of the symptoms and cure, illustrated by histories of cases, amongst which he mentions a girl who, being bitten by this insect, could be cured only by the music of a drum; relating also that a Spaniard, trusting to the efficacy of the music, submitted to be bitten in the hand by two of these spiders of different colours, and possessed of different qualities. The venom was no sooner diffused about his body than the symptoms of the disorder began to appear, upon which harpers, pipers, and other musicians were sent for, who, by various kinds of music, endeavoured to rouse him from that stupor into which he was fallen; but here it was observed that the bites of the two insects had produced contrary effects, for by one he was incited to dance, and by the other he was restrained therefrom; and in this conflict of nature the patient expired.

Some authors indeed have carried their belief in this matter so far as to note down the tunes which they believed most serviceable for the *Tarentolati*, as persons suffering under tarentismus were called. Professor Haffenreffer, of Ulm, has set them forth in his work entitled "*Traité des Maladies de la Peau*."

It is in the Philosophical Transactions of our own country that we find the first attempts to disprove this fiction. So far back as 1672, a letter from Dr. Cornelio, a Neapolitan physician, was published, in which it is stated that "all those that think themselves bitten by *Tarantulas*, except such as for evil ends feign themselves to be so, are for the most part young wanton girls, whom the Italian writers call *Dolci di Sale*, who by some particular indisposition, falling into this melancholy madness, persuade themselves, according to the vulgar prejudice, that they have been stung by a *Tarantula*."

A century afterwards, in the same Transactions (for 1770), Professor Dominico Cyrillo, of Naples, states, that having had an opportunity of examining the effects of this animal in the province of Tarento, where it is found in great abundance, he finds that the surprising cure of the bite of the *Tarantula* by music, has not the least truth in it; and that it is only an invention of the people, who want to get a little money by dancing, when they say the tarentism begins. He adds, "I make no doubt but sometimes the heat of the climate contributes very much to warm their imaginations, and throw them into a delirium, which may be in some measure cured by music; but several experiments have been tried with the *Tarantula*, and neither men nor animals have had any other complaint than a very trifling inflammation upon the part like that produced by the bite of a scorpion, which goes off by itself without any danger at all. In Sicily, where the summer is still warmer than in any part of the kingdom of Naples, the *Tarantula* is never dangerous, and music is never employed for the cure of the pretended tarentism."

The correctness of these remarks has been fully confirmed by several cases recently brought under the notice of the Entomological Society of France, by M. Lefebvre, and published in the *Annales* of that Society.

TARDIGRADA — Slow-goers. A family of mammalia of the order *Edentata*, including, of living animals, the sloths (see *AI* and *UNAO*), which are tree animals of moderate size, and the extinct *Megatherium* and *Megalonyx*, both of which have been animals of giant bulk; but their habits and the charac-

ters of the countries in which their bones are found, at the time when the animals were alive, are not known. The skeletons of some of them have been found in a much more perfect state than those of most extinct animals, the *Megatherium* in particular; and its remains are such as to show that it had been by far the largest and heaviest land animal of which we have any knowledge. The skeleton of an elephant seems weak and feeble beside it; and there is more matter in some of its single bones than in all the bones of the human body.

TARENTULA (Fabricius, Latreille). In the commencement of the article **TARANTULA**, we have said that this name, although strictly applicable to the *Tarantula* of Tarentum, had been employed for other large species of arachnidous animals. And Brown having misapplied it in his History of Jamaica to the Linnæan *Phalangium reniforme*, belonging to the modern genus *Phrynus* of Olivier; Fabricius, unaware of the establishment of the latter genus, employed the name *Tarantula* for the species of *Phrynus* and *Thelyphonus* (Latreille, see **PHRYNUS**); which name, *Tarantula*, Latreille has injudiciously retained in the Règne Animal; although for the two subgenera he preserved the names *Phrynus* and *Thelyphonus*.

TARUS (Clairville; CYMINDIS, Latreille). A genus of coleopterous insects, belonging to the family *Carabidæ*, and subfamily *Brachinides*, of moderate size and depressed form; the thorax is cordate truncate; the body oblong; the maxillary palpi filiform; and the labial terminated by a large hatchet-shaped joint, at least in the males; the head is not narrowed behind into a neck, and the tarsi are not dilated. The type of the genus is the *Carabus humeralis* (Marsham), pitchy black, with the humeral angles of the elytra reddish. The species are of rare occurrence, and are found beneath stones. Stephens describes eight as inhabitants of Britain.

TAXUS (Linnaeus). A genus of three species and several varieties of evergreen trees, belonging to the natural order *Coniferae*. This is the well-known yew, a native of Britain, remarkable for its longevity, the toughness of its young branches, and durability of its timber. It is moreover remarkable for its poisonous effects on cattle that eat the twigs, especially after these have been a little dried: cattle bred where yew-trees grow, are never hurt by browsing it green. The tree yields seeds plentifully, and by which seedlings are raised.

TECOMA (Jussieu). A fine ornamental genus of evergreen and deciduous shrubs and climbers, natives chiefly of North and South America. The flowers are didynamous, and the genus belongs to *Bignoniaceæ*. *Tecoma Capensis*, and *Grandiflora*, are favourite greenhouse climbers, and easily propagated by cuttings.

TECTONA (Linnaeus). A genus of a single species, belonging to *Verbenaceæ*. It is one of the largest timber trees of India, and rivalling the British oak for bulk as well as durability. It is propagated by cuttings in stoves.

TELEPHIUM (Linnaeus). A genus of only one species as yet described, bearing pentandrous flowers, and belonging to *Portulacææ*. This is the *Orpine* of English authors (though the *Sedum telephium* is the true *Orpine* of English fields), and is introduced into the flower garden for embellishing rock-work.

TELEPHORIDÆ (Leach). A family of coleopterous insects, belonging to the section *Pentamera*, and subsection *Serricornes*, and nearly related to the family of the glow-worms (*LAMPYRIDÆ*, which see), from which they are distinguished by having the body in both sexes always furnished with wings, and by the maxillary palpi being scarcely longer than the labial; the body is long and rather narrow, and of a soft consistence; the antennæ are moderately long and slender.

By Linnaeus, the name of the blister-fly (*Cantharis*), was inappropriately applied to these insects, which are still described under that name by many systematic writers; whilst by others they are called *Telephorus*, which name was given to them by Schaeffer, and which they ought to retain. By Geoffroy they were constituted into the genus *Cicindela*. They make their appearance in the early summer months, abounding in our gardens and hedges, and are well known to children under the name of soldiers and sailors, probably on account of their different colours, red, buff, and blackish-blue, being their chief hues. Their flight is slow and heavy. The larvæ are black, and of a velvety appearance, with the legs, antennæ, and palpi reddish; they are rather long, depressed, and of a soft consistence; the head is scaly, and the mandibles are very robust; beneath the terminal segment of the body there is a fleshy retractile appendage which the insect employs whilst in motion as a seventh leg. They reside in moist earth, and feed upon other insects. In the perfect state also they are insectivorous.

It has been recorded, that in certain seasons during winter, a great extent of the snow with which the ground was at that time covered in various parts of Sweden, swarmed with the larvæ of these insects, as well as with other living insects; and it has been supposed that these creatures had been raised and transported by sudden gusts of wind during the violent tempests which overthrew many of the large trees, especially of the fir tribe, in those countries. Such has been regarded as the origin of what has been called "showers of insects." The species discovered in such situations, and occasionally even upon the frozen lakes of the country, are probably those which make their appearance early in the year. The name of the genus *Telephorus* is derived from the Greek, and is given to these insects in allusion to their habits of killing and devouring other insects.

The genera are *Telephorus*, *Silis*, and *Malthinus*. In the first the elytra are of the ordinary size, with the margins of the thorax entire. The second differs in having the posterior angles of the thorax notched; and the last has the elytra abbreviated. The typical genus *Telephorus* is very extensive, there being nearly forty British species. The type is the *Cantharis rusticus* of Linnaeus. The *Cantharis lividus*, *rufus*, *fuscus*, *obscurus*, of Linnaeus, are also common species.

TELLURIUM, a mineral usually found combined with gold and other metals of a less valuable character. In the native state it is blended with iron and gold, the latter being in very small quantities. The ores of *Tellurium* are only found in the mines of Transylvania and in Siberia. Dr. Clarke has given a long account of the *Tellurium* mines in the fourth volume of his Travels.

TELOPEA (Dr. R. Brown). A genus of a single species, and one of the most magnificent flowering

trees found in Australia. The flowers belong to Linnæus' fourth class, and to the natural order *Proteaceæ*. It is the *Waratah* of the natives; and the utmost skill of our practical botanists has been exerted to flower this fine plant, and they have succeeded by growing them in a compost of light loam, heath-mould, and sand; keeping the pots well drained, and in an airy situation in a greenhouse, and watering them cautiously. They are raised chiefly from imported seed; but they may be also increased by cuttings planted in sand but not at a high temperature.

TENEBRIONIDÆ (Leach). A family of coleopterous insects, belonging to the section *Heteromera*, and division *Melasoma*, distinguished by having the body furnished with wings (of which the *Pimeliidæ* and *Blapsidæ* are destitute). The body is oval or oblong, depressed, or but slightly elevated, with the thorax square or trapezoid, and as broad behind as the base of the elytra; the palpi are dilated at the tips, the terminal joint of the maxillary being triangular or hatchet-shaped; the mentum is narrowed at the base, leaving the maxillæ exposed.

By Linnæus, the families *Tenebrionidæ*, *Blapsidæ*, and *Pimeliidæ*, were all included in the genus *Tenebrio*, which takes its name from *tenebra*, darkness, and is given to them in allusion to their darkling habits. By Fabricius, the genus *Tenebrio* was restricted to the insects of the present family, and by the still further restriction of modern authors, the name is generically confined to the meal-worm beetle, *Tenebrio molitor* of Linnæus. The other genera are *Crypticus*, *Epitragus*, *Opatrum*, *Toxichum*, *Sarrotrium*, *Chiroscelis* and *Upis*. Mr. Stephens adds *Diaperis* and some other genera placed by Latreille in the division *Taxicornes*, as well as *Stene*, *Usoma*, *Alphitobius*, *Pedinus*, and several other allied genera.

The typical genus *Tenebrio*, as now restricted, comprises those species which have the body elongate, rather narrow, and sub-depressed; the thorax is broader than long; the upper lip is coriaceous and entire; the antennæ have the five terminal joints rather depressed and thickened, and the fore legs simple. These insects delight in obscure situations, hence their colours are of corresponding hues. They chiefly frequent the lower rooms of houses, cellars, &c., in moist situations, especially delighting in bake-houses, corn-mills, and other places where wheat is kept, upon which the larvæ feed; these larvæ are termed meal-worms, and are well known to bird-fanciers as a favourite food of the nightingale and other cage birds, and by whom they are reared in great quantities; it is essential, however, to have the tops of the pans in which they are kept closed with a leaden cover, as they will make their way through wood. These larvæ are cylindrical, about an inch in length, very smooth, of a shining yellowish red colour, composed of twelve scaly segments exclusive of the head, which is rather depressed, and furnished with two mandibles, antennæ, and very minute palpi; each of the three anterior segments of the body is furnished with a pair of short scaly legs; the terminal segment is conical, with two small brown hooks, and furnished on the under side with a fleshy retractile proleg, which is employed by the insect when in motion as an extra leg. The meal-worm changes its skin several times; it avoids the light, and when exposed in the midst of its food, it immediately endeavours to burrow itself into the adjacent biscuit or flour in which it has taken up its abode. After the last shedding of its

skin, it appears as a pupa, without having constructed any cocoon. After remaining about six weeks in this state the perfect insect makes its escape from the pupa skin, being at first of a pale reddish colour; it soon, however, attains its ordinary black hue. It immediately seeks its partner, and wanders but little from the situation in which it was reared. This is the typical species of the genus, and is the *Tenebrio molitor* of Linnæus; it varies in length from five to eight lines, is of a brownish-black colour above, dark pitchy-red beneath; the thorax as broad as the elytra, with two posterior impressions, and the elytra are finely punctured and striated.

There are three other British species; one of which, *T. lævis*, Stephens, is unique in the collection of the writer hereof.

According to M. Lacordaire, *Tenebrio gigas* (an inhabitant of Brazil, where it resides under the bark of trees), ejects a caustic fluid from the extremity of the body when disturbed, to the distance of nearly a foot. Other smaller species of the same country cover themselves entire with the same matter.

TENOIDÆ, or **TENOIDÆ**, the ribbon-fish family. The eighteenth family of those into which Cuvier divides the spinous-finned fishes. In their characters they approach pretty near to the mackerel family; but they differ much in shape. They are very long in the body, and flattened in the sides, and have the scales small. They are divided into three tribes or sections.

1. The muzzle long, the gape deep, the lower jaw projecting beyond the upper, and the teeth large. There are two genera: *Lepidopus*, with the ventral fins in the shape of two scaly plates, the body long and slender, a dorsal fin along the whole length, a low anal fin, and a well-formed caudal. *Trichiurus* have the mouth, teeth, and general form of the body the same, but no ventrals or caudal, and the tail drawn out in the form of a slender thread.

2. The muzzle short, and the gape small. Of these also there are two genera: *Gymnotus* have no anal, but a long dorsal, with the anterior rays produced, and forming a sort of tuft; the ventrals long, and the tail ending in a sort of hook; they can crawl and climb; their flesh is soft, and decays rapidly. *Stylophorus* have the general characters of the other, but the tail drawn out into a slender filament longer than the body.

3. The muzzle short, and gape opening obliquely. Of these also there are two genera: *Cephala* (ribbon fishes), the dorsal and anal fins long, extending to the base of the caudal, which is also well developed. *Lophotis*, the head with an elevated bony crest, to which a long and strong spine is articulated, with a membrane on the posterior edge, the opening of the mouth directed upwards, and the eyes very large.

All these fishes are remarkable for the slenderness and thinness of their bodies as compared with the length; some of them have a rich metallic lustre, and appear like silver ribbons.

TENTHREDO (Linnæus; or rather **TENTHREDINIDÆ**, Leach). A family of hymenopterous insects, known under the ordinary name of saw-flies, distinguished by having the abdomen attached to the thorax by its entire breadth, by the organs of oviposition not being exerted, and by the form of the larvæ, which, instead of being footless grubs, like the maggots of wasps, &c., are provided with a great number of legs, resembling the caterpillars of lepidopterous insects.

Under the article **SAWFLY** we have given various details relative to the natural history and structural peculiarities of these insects, reserving for the present article the technical details of the family.

The mandibles are generally elongated and compressed, the lower lip divided into three fleshy lobes, the maxillary palpi always long, and composed of six joints, and the labial four-jointed and short; the wings large, and exhibiting numerous cells; the abdomen cylindrical and nine-jointed; behind the scutellum are to be observed two small rounded bodies, generally differently coloured: the antennæ are very variable in their construction; in some being long, slender, and cylindrical; in others short and terminated by a large knob; in others three-jointed, the third joint consisting of a long and cylindrical club; and in others beautifully pectinated or ramose. The structure of the saws, which are in fact the chief characteristic of the groups, is detailed in the article above referred to.

The family is exceedingly numerous, the species generally of large or moderate size; and the colours often handsomely varied. They are entirely herbivorous in the larva state, occasionally doing much mischief.

The genera are numerous. Those of *Perga*, *Syzygonia*, *Pachylosticta*, and *Cimbex* (from which last Dr. Leach has separated many of the species, under the names of *Trichiosoma*, *Amasis*, *Zaræa*, *Abia*, &c.) have the antennæ short and clubbed. The genera *Hylotoma*, *Schizocerus*, and *Ptilia*, have the antennæ three-jointed and terminated by a long cylindrical club; those of the males of *Schizocerus* are divided into two long equal branches. The restricted genus *Tenthredo*, together with *Allantus*, *Dolerus*, *Nematus*, *Pristiphora*, *Selandria*, *Fenusia*, *Dosytheus*, *Emphytus*, *Cræsus*, *Cladius*, &c., have the antennæ simple, and generally nine-jointed. In *Pterygophorus* and *Lophyrus* the antennæ are deeply bipectinated in the males, and in the genera *Tarpa* and *Lyda* they are long, setaceous, and multiarticulate; the genera are also distinguished by the variable number of the cells of the upper wings.

The genus *Tenthredo*, as restricted by a late writer, comprises those species which have nine-jointed antennæ, with the third joint of the same length as the fourth, and with two marginal and four sub-marginal cells. Stephens describes about thirty British species, the type being the *Tenthredo Rapæ* of Linnæus.

TENUIROSTRES—Slender-billed birds. A family of the order *Passeres*, comprising the nut-hatches, creepers, humming-birds, and hoopoes. They differ much in their appearance and habits. See **BIRD**.

TEPHRITIS (Latreille; ΤΡΥΠΕΤΑ, Meigen). A genus of dipterous insects, belonging to the family *Muscide*, having the abdomen terminated by an elongated, cylindrical, and exserted tube; the head is transverse and rounded, the antennæ short and three-jointed, the seta at the base of the third joint being naked, or scarcely pubescent; the alulae small, the wings vibratile when in action, but laid flat upon the back when at rest. These flies are very beautiful, owing to the ornamental markings of the wings, which are varied with bars, circles, stars, &c., of endless variety of form. They are generally found upon composite flowers in the hot summer months, the females depositing their eggs amongst the seeds of those plants upon which the larvæ feed. Some species,

however, introduce their eggs into the epidermis of the same plants, producing large galls of various sizes. Such is the case with *Tephritis cardui*, the type of the genus, which is the cause of the formation of the large galls often observed upon thistles. According to M. Catoire, the inhabitants of the Isle of France are scarcely able to obtain sound oranges, in consequence of the attacks of a species supposed to belong to this genus, but which we should rather conceive to be the *Ceratites citriperda* of MacLeay. (Zool. Journ.)

TEPHROSIA (Persoon). A genus of plants of very various habit; viz., shrubs, undershrubs, and herbs, scattered over every quarter of the globe. The flowers are diadelphous, and belong to *Leguminosæ*. They are nearly allied to the genus *Galega*.

TEREBINTHACEÆ. A large natural order, containing twenty-seven genera, and one hundred and forty-two species already described. There is so much diversity in the structure and qualities of the plants here associated, that botanists have found difficulty in making the order purely congeneric; this circumstance has caused the order to be separated into seven tribes, namely, *Anacardiaceæ*, *Sumachineæ*, *Spondiaceæ*, *Burseraceæ*, *Amgrideæ*, *Spatheliaceæ*, and *Conmaraceæ*. The general character of the order is that the different genera are resiniferous, with mostly exstipulate dotted leaves, and imbricate ostivation of the calyx; superior ovaries, few in number, exalbuminous seeds, and the radicle of the embryo turned towards the hilum. It contains many useful and economical plants, as the cashew and pistachio nuts, the spondias and mangos of India. The *Balanodendron*, *Iceia*, *Amyris*, *Rhus*, and *Melonorrhæa*, are all plants yielding valuable resins, gum, varnish, &c., useful in the arts. Several of the genera and species are hardy, and all may be propagated by layers, cuttings, or seeds, as described under the various genera.

TEREBRANTIA (Latreille). A primary section of the *Hymenopterous* order of insects. See **HYMENOPTERA**.

TERMINALIA (Linnæus). A genus of ornamental trees, natives of India. The flowers are polygamous, and the genus belongs to *Combretaceæ*. *T. vernix* affords a resinous juice that is used in China as a varnish, and *T. Catappa* yields a black pigment, with which the Indians dye their cloth. In our collections these plants are increased by cuttings.

TERMITIDÆ (Termes, Linnæus). A very extensive and at the same time destructive tribe of insects, placed by Linnæus in the order *Aptera*, on account of the apterous condition of some of the individuals, whilst the winged individuals he regarded as belonging to the order *Neuroptera*, placing them in the genus *Hemerobius* (*H. testaceus*). The small insects comprising the family *Psocidæ* of Leach (which see), were also placed by Linnæus in the genus *Termes*.

These insects are well known under the name of white ants, and are distinguished from other neuropterous insects by having the tarsi composed of four joints, the three basal joints being very small, the wings laid horizontally upon each other over the back when at rest, and far exceeding the length of the body, the head is rounded, the pro-thorax square or semicircular and depressed, as is the general form of the body; the antennæ are short, the mouth armed with strong dentate jaws, galeated maxillæ, and a quadri-lobed lower lip (thus very closely resembling

the mouth of the *Orthoptera*); the ocelli are three in number, placed on the forehead, the anterior one being not so distinct as the others; the wings are but slightly transparent and coloured, with the anterior margins incrassated, and the nerves very distinct, and not forming the beautiful net-work observed in other tribes of neuropterous insects; the abdomen is terminated by two minute conical two-jointed styles, and the legs are of moderate length and slender.

These insects, with the exception of one or two small species, are strangers to Europe, and most fortunate is it that such is the case, for their devastating powers, in the torrid zone, is immense; furniture, wood-work, and merchandise of all kinds, is attacked, and in a very short space of time entirely destroyed; nothing, in fact, escapes their destructive energies except metal and stone. Residing ordinarily on the ground, they form their burrows with such care and precision that they make a place of exit just beneath the feet of chairs, tables, &c., where these articles are suffered to remain stationary for any length of time; and then by working upwards they completely excavate the piece of furniture, leaving only the external pellicle. All this is effected without their presence being suspected, or in any manner indicated. In a very short time the supports of the piece of furniture are rendered so weak that it tumbles to pieces, crumbling to dust at the touch.

The African species of this genus have long attracted the attention of travellers, on account of the size and remarkable construction of their nests, but it was reserved to Smeathman to give the most complete and satisfactory account of their singular economy and habitations, and which was published by him in the Philosophical Transactions for the year 1781.

These nests may be said to surpass those of bees, wasps, beavers, and other animals, in the same proportion as the habitations of the most polished European nation excel the rude huts of the inhabitants of those countries where the termites abound; whilst, in regard to their size, it is certain that if the dwellings of mankind were of the ordinary size of the Egyptian pyramids, they would sink in comparison with the labours of these insects. The chief work of the construction of the nests of the white ants falls upon a distinct class of labourers, somewhat analogous in this respect to the workers of the hive, but these labourers are apterous and in the state of larvæ, not exceeding a quarter of an inch, but the structures which they erect are ten or twelve feet above the surface of the earth. Supposing a man's ordinary height to be six feet, Mr. Smeathman calculates that the building of these insects may be considered, relative to their size and that of man's, as being raised to near four times the height of the largest of the Egyptian pyramids, that is, corresponding with considerably more than half a mile! With respect to their interior construction, and the arrangement of the different parts of the building, they do not fall short of any human construction.

It will be necessary, however, before giving an account of the internal parts of the nest, to describe the different members of which the community is composed. Smeathman had described these different kinds of individuals; but it is to Latreille that we are indebted for a more precise account, this author having minutely investigated the economy of a species which inhabits the south of France, and of which

the writer hereof saw a nest, with the inhabitants in full activity, in the city of Berlin, in the possession of Dr. Burmeister, (*T. lucifugum*). The community at large surpasses all calculation, far exceeding those of the ants or the bees.

The workers or labourers above mentioned nearly resemble the perfect insects, of which, in their ordinary winged state, a description has already been given; they are, however, smaller, with the body soft, and destitute of wings; the head is also larger, but is not apparently furnished with the least trace of eyes, a most remarkable circumstance, when the labour of this class of the inhabitants is taken into consideration. It is the duty of these insects to construct the nest, which is composed of agglutinated sand and earth, of varied form, being conical, turreted, cylindrical, &c.; to form roads, or rather covered-ways, diverging in all directions from the nest, and leading to every object of plunder within their reach; to attend at the proper time to the duties of the royal couple, and to take care of the eggs. The workers, we have said, are larvæ.

The pupæ first described by Latreille are very much like the larvæ, but they have rudiments of the four wings visible. In the nest of a small African species examined by the writer hereof, the pupæ so much resembled winged frog-hoppers (*Tettigonia spumaria*), that several entomologists were completely deceived at first sight on inspecting them. It has not been stated what share of labour falls to these pupæ.

The perfect insects differ from the workers in being furnished with wings, and in having the head rather smaller, although the general size is larger; their general appearance is indeed so unlike that of the workers that it is not surprising that Linnæus should have introduced them into different orders, although, if the structure of the mouth had been examined, their relationship would have been discovered. They are not to be discovered in the nest till just before the commencement of the rainy season, when they undergo their last change, preparatory to the formation of new colonies. There is a very great analogy in respect to the impregnation and subsequent treatment of these insects and the ants and bees, especially the former of these industrious tribes; like them the winged termites quit the nest soon after they have attained the perfect state, swarming in prodigious numbers during the evening or night, according to Latreille, during which period we may from analogy conclude that pairing takes place, although, according to Smeathman, this takes place afterwards. On reaching the ground again the wings of the termites fall off, as is also the case in the female ants, and they now become the prey of innumerable birds, reptiles, and insects; so that probably but very few pairs, out of the countless myriads, of which the swarm had consisted, contrive to escape, so as to lay the found-

dation of fresh colonies. At this period they are also eaten by the Africans; and Smeathman says they are delicate, nourishing, and wholesome, when merely roasted in the manner of coffee, without any sauce or other help from cookery. The same author informs us, that the few fortunate pairs which happen to survive this annual massacre and destruction, and are found by the labourers, which are continually running about on the surface of the ground, are by them elected *Kings and Queens* of new states, and are immediately protected from their innumerable enemies, but with the loss of their liberty and ultimately of their lives, being enclosed by the workers in a chamber of clay, "where the process of propagation soon commences." The young queen of the hive-swarm is followed by a portion of the community, and the female ant, after swarming, and the loss of her wings, is guarded by the worker ants; there is therefore so much analogy in these circumstances, that we are almost tempted to consider that Smeathman must have erred in stating that the working termites imprison both the king and queen terms. That it should be necessary for the latter to be carefully guarded will be very evident, but why the king, in his helpless and wingless state (for we consider that the loss of wings is consequent upon and not precedent to pairing), should be shut up, seems questionable. We make these observations with hesitation, because Latreille (*Règne Animal*, v. 5, p. 255, 2nd edit.), and Kirby and Spence (*Introd.* vol. 2, p. 35) seem to adopt, without any hesitation, this statement of Smeathman.

3, Queen in the first or winged state. 4 Ditto, filled with eggs.

Soon after the imprisonment of the captured queen a great change takes place in her appearance. The abdomen, which at first was of the ordinary size, now increases in bulk, and at length becomes of such an enormous size as to exceed the bulk of the rest of her body 1500 or 2000 times. She becomes a thousand times heavier than her consort, and exceeds 20,000 or 30,000 times the bulk of one of the workers; in this state the matrix has a constant peristaltic or undulating motion, in consequence of which eggs, to the number of 80,000, are discharged in the course of twenty-four hours.

There still, however, remain to be noticed another class of inhabitants, which are totally unlike any other of the inhabitants, and of which there is no analogous example in any of the other tribes of insects; these are called *neuters*, although Fabricius erroneously considered them as *pupæ*. Smeathman calls them soldiers, from their duties in the nest, observing, that they have been supposed by some

authors to be males and the workers to be neuters, but that they are in fact the same insects as the workers, only they have undergone a change of form, and approached one degree nearer to the perfect state; but this opinion is opposed by Latreille, in consequence of the large size of the head and the want of rudimental wing-cases, which would be exhibited were the soldier insects in the pupa state. Kirby and Spence think the soldiers may possibly be the larvæ of the males. Huber seems to doubt their being neuters. They are much less numerous than the workers, being in the proportion of one to one hundred, and considerably exceeding them in size; they are destitute of wings, and have no trace of the rudimental wing covers of the pupæ; the head is very large and horny, and armed with very long slender curved jaws; their duty is to guard the nest when attacked, for which purpose they are stationed nearer to its exterior surface, and they present themselves the first in case of a breach made in the walls; they bite with considerable force, and it is said they impel the workers to their labour when they are inclined to be lazy. It would be very interesting for persons abroad, having opportunities for so doing, to endeavour to discover what are the earliest stages of these soldiers' existence, in order to ascertain whether they remain permanently apterous, being, like the wingless specimens of *Velia currens*, figured in the article *INSECT*, retarded in their transformations, their development being stopped short before their arrival at maturity, and thereby gaining an enlarged head, in order to compensate for their ultimate want of wings.

Such are the different classes of a community of white ants. Their habitation now requires more particular description. The forms of their nests are varied according to the species by which they are formed. The *Termes fatale*, Linnæus, (*Bellicosus*, Smeathman), whose history has been most especially

noticed, forms the largest nests, being, as above mentioned, ten or twelve feet in height, of a conical form, with numerous conical turrets on its sides; this is formed of clay, and being soon coated with growing grass, very much resembles a hay-cock. *Termes atrox* and *mordax* build cylindrical pillars three quarters of a yard high, with a projecting conical roof; whilst *T. destructor*, Fabricius, (*Arborem*, Smeathman), constructs its nests of different sizes amongst the branches of trees often seventy or eighty feet high. Of the strength of these erections Smeathman's account enables us to form a clear notion. When raised to little more than half their height, it is the practice of the wild bulls to stand as sentinels upon them, whilst the rest of the herd is

remaining below. When at their full height of ten or twelve feet, they are used by the Europeans as places to look out from over the top of the grass, which grows, upon the average, thirteen feet high. Indeed, Mr. Smeathman himself stood with four men on the top of one of those erections, in order to obtain a view of any vessel which might come in sight.

Fig. 7. Section of the nest of *Termes fatale*, on a scale of one inch to eight feet: *a*, the royal chamber; *b*, the apartments of the royal attendants; *c*, the nurseries and magazines extending up the sides of the nest; *d*, the lower roof; *e*, the upper roof; *f*, two bridges reaching from apertures in the lower roof to some of the upper nurseries; *g*, the hollow dome; *h*, *h*, the thick mud walls of the building, penetrated in various directions by passages; *i*, of various sizes, chiefly in a spiral direction from the bottom of the nest to the upper parts; *k*, one of the great under-ground outlets of the nest.

The following account of the interior arrangement of the nest is descriptive of that of *Termes fatale* observed in Guinea, and other parts of the western coast of Africa, by Mr. Smeathman:—On making a longitudinal section of the nest, it is perceived that the lower portion of the building alone serves for the habitation of the community, the upper part forming an immense dome, serving not only as a defence against the weather, but keeping up a genial warmth in the inhabited parts of the nest, and which consists of the royal chamber, the nurseries for the young, the storehouses for food, and innumerable galleries, passages, and empty spaces. The royal chamber is placed in the centre of the building, nearly on the level of the ground. At first it is only about an inch long, and of a semi-oval form; but, as the queen increases in size, the apartments surrounding it are pulled down, and the space thrown into that of the queen's chamber, until it is eight inches or more in length; but, in order to prevent the escape of the queen, the entrances into this chamber are so small that workers only can enter. Around the royal chamber, and extending on all sides a foot or more, are an innumerable quantity of arched rooms, of different shapes and sizes, for the accommodation of the attendants and soldiers whose duty it is to wait on the queen. Smeathman calls these the royal apartments. Then come the nurseries or egg-chambers and the food magazines. The former, in the early stage of the colony, are ranged close to the royal chamber; but when the queen has attained a much larger size, the space required for her enlarged chamber, and for the apartments of her additional attendants, extends so much farther, that the nurseries are removed to a greater distance, being composed entirely of wooden materials, seemingly joined together with gums. Into these the attendant workers immediately carry the eggs produced by the queen, lodging them there as fast as they can obtain them

from her, and communicating with each other by empty passages on all sides. In these nurseries Mr. Smeathman was induced to believe that the ants formed a kind of garden for the cultivation of a species of microscopical mushroom, appearing like a kind of mould, among which arise numerous globules about the size of a pin's head; and Mr. König, who published an account of the East Indian *Termites*, considered that this is the food of the larvæ, or very young insects, probably before they are sufficiently strong and active to leave the nest. The cares of the community for the education of the young progeny is necessarily rendered much less irksome than it is in the case of the bees or ants, because in those insects the larvæ and pupæ are inactive, and totally unable to provide for themselves; but in the *Termites* the whole period of the insect's existence, immediately after its bursting from the egg, is one of activity, the pupa not being quiescent, as in some other of the neuropterous insects.

The provision-cells are arranged without much seeming order amongst the vacant passages which surround the nurseries; they are chambers of clay, always well stored with provisions, consisting of bits of wood, gums, and the inspissated juices of plants. These cells, with the nurseries, are extended up the sides of the dome, reaching to about one-third from the top, and leaving an open area in the middle under the dome. At the top of the nurseries is extended a flatish roof, impervious to the wet, should the upper part be damaged. The lower part of the area, also above the royal chamber, has a flatish roof, also water-proof. Above the upper of those roofs the dome is hollow, but the outer walls of the nest are of very great thickness, and perforated with numerous passages, running from the top to the bottom of the walls in various winding directions, intersecting each other at different heights, and opening either immediately into the dome, in different places, and into the lower half of the building, or communicating with every part of it by other smaller circular or oval galleries of various diameters. The main underground galleries, by which egress and ingress to the nest is effected, are a foot in diameter, and run in a sloping direction under the bottom of the nest to the depth of three or four feet, where they branch out horizontally on every side, and are carried underground, near to the surface, to a very great distance. Besides the passages reaching from the lower to the upper magazines and nurseries, bridges of a single arch, of great extent, are built from the upper side of the lower roof above mentioned, and reaching to the upper apartments. Two of these are represented in the annexed engraving. By the assistance of these bridges a great saving of labour, in transporting the eggs to the upper nurseries, is effected.

Of the operations of these insects, in the construction of their abode, some idea may be obtained from the recital of the circumstances subsequent to the making of a breach in any part of their outer wall. One of the soldiers first makes its appearance, and walks about the breach as if to see whether the enemy be gone, and to discover whence the attack proceeds. In a short time two or three others appear, and soon afterwards a more numerous body, who rush out as fast as the breach will permit them, their numbers increasing so long as any one continues to batter the building. During this time they

are in the most violent bustle and agitation ; while some are employed in beating with their mandibles upon the building, so as to make a noise which may be heard at three or four feet distance. On ceasing to disturb them, the soldiers retire, and are followed by the labourers, who hasten in various directions towards the breach, each with a burden of mortar in its mouth ready tempered. Though there are millions of them, they never stop nor embarrass each other, and a wall gradually arises which fills up the chasm. A soldier attends every 600 or 1000 of the labourers, seemingly as a director of the works, for he never even touches the mortar. One in particular places himself close to the wall which they are repairing, and frequently makes the noise above mentioned, which is constantly answered by a loud hiss from all the labourers within the dome, and at every such signal they immediately redouble their pace, and work as fast again. The obstinacy of these soldiers is remarkable ; they fight to the very last, disputing every inch of ground so well as often to drive away the negroes, who are without shoes, making even the white people bleed profusely through their stockings.

It is of course impossible for us to enter into the numerous details of the economy of these insects recorded by Smeathman, König, and others. Our sketch, though slight, has comprised the most material points in their very peculiar economy ; but we cannot close this article without quoting Mr. Smeathman's admirable observations upon the general effects in the economy of nature at large of the presence of these and other similarly obnoxious creatures. They are the observations of a true naturalist, who had had ample opportunities of seeing and judging of their action.

"It may appear surprising how a Being perfectly good should have created animals which seem to serve no other end but to spread destruction and desolation wherever they go. But let us be cautious in suspecting any imperfection in the Father of the universe. What at first sight may seem only productive of mischief, will, upon mature deliberation, be found worthy of that wisdom which planned the most beautiful parts of the world. Many poisons are valuable medicines—the storms are beneficial—and diseases often promote life. These *Termites* are indeed frequently pernicious to mankind, but they are also very useful, and even necessary. One valuable purpose which they serve is to destroy decayed trees and other substances, which, if left on the surface of the ground in hot climates, would in a short time pollute the air. In this respect they resemble very much the common flies, which are regarded by mankind in general as noxious, and at best as useless beings in the creation. But this is certainly for want of consideration. There are not probably in all nature animals of more importance ; and it would not be difficult to prove that we should feel the want of one or two species of large quadrupeds much less than of one or two species of these despicable-looking insects. Mankind in general are sensible that nothing is more disagreeable or more pestiferous than putrid substances ; and it is apparent to all who have made observation that those little insects contribute more to the quick dissolution and dispersion of putrescent matter than any other. They are so necessary in all hot climates, that, even in the open fields, a dead animal, or small

putrid substance, cannot be laid upon the ground two minutes before it will be covered with flies and their maggots, which, instantly entering, quickly devour one part, and, perforating the rest in various directions, expose the whole to be much sooner dissipated by the elements. Thus it is with the *Termites*. The rapid vegetation in hot climates, of which no idea can be formed by anything to be seen in this, is equalled by as great a degree of destruction from natural as well as accidental causes. It seems apparent, that when anything whatever has arrived at its last degree of perfection, the Creator has decreed that it shall be totally destroyed as soon as possible, that the force of nature may be speedily adorned with fresh productions in the bloom of spring or the pride of summer ; so, when trees, and even woods, are in part destroyed by tornadoes or fire, it is wonderful to observe how many agents are employed in hastening the total dissolution of the rest. But in the hot climates there are none so expert, or who do their business so expeditiously and effectually, as these insects, which, in a few weeks, destroy and carry away the bodies of large trees, without leaving a particle behind ; thus clearing the place for other vegetables, which soon fill up every vacancy ; and in places where, two or three years before, there has been a populous town, if the inhabitants, as is frequently the case, have chosen to abandon it, there shall be a very thick wood, and not the vestige of a post to be seen, unless the wood has been of a species which, from its hardness, is called iron-wood."

TERN. See STERNA.

TERNSTRÆMIACEÆ. A small natural order, comprising eleven genera and nineteen species ; small as it is, it consists of five tribes, namely, *Ternstræmiaceæ*, *Frezieraceæ*, *Sauraujeæ*, *Laplacææ*, and *Gordoniææ*. The plants associated here are all trees or shrubs, bearing handsome white or yellowish flowers ; they are nearly related to *Camellieæ*, from which they do not differ at all in habit. The greater number have a place in botanical collections, and are propagated by cuttings, layers, or grafting.

TESTUDINARIA (Burchell). A curious genus of African plants, bearing small diœcorous flowers, and belonging to the natural order *Dioscoreaceæ*. This is the elephant's-foot of travellers, so called from its large tuberous stem, resting on the surface of the ground, sending up annually a number of slender twining stems, and a fringe of fibrous roots downward. Young plants are imported from the Cape.

TETRAGONIA (Linnæus). A genus of herbs and undershrubs, chiefly natives of the Cape of Good Hope. The flowers are icosandrous, and being of a succulent habit belong to the natural order *Ficoideæ*. Like other succulents they are easy of propagation. One of the annual species is the *T. expansa*, or New Zealand spinach, a culinary vegetable lately introduced into our kitchen gardens.

TETRAMERA (Latreille). One of the primary divisions into which the coleoptera are arranged by the French authors, distinguished by having apparently only four joints in all the tarsi, but in reality having a fifth minute joint interposed between the last and the preceding joint, being often hidden between the lobes of the latter. The subsections belonging to this section are the *Rhyncophora* (types, *Bruchus*, *Attelabus*, and *Curculio*, Linnæus) ; *Xylophaga* (type, *Scolytus*, Geoffroy) ; *Longicornes* (types, *Cerambyx* and *Leptura*, Linnæus) ; and *Cyclica* (type

Chrysomela, Linnæus). The *Clavipalpes* of Latreille seem more naturally to be allied to some of the fungivorous *Necrophagous pentamera*.

TETRAMERIUM (Gærtner). A genus of West India evergreen shrubs, belonging to the fourth class of Linnæus, and to the natural order *Rubiaceæ*. The genus is nearly allied to *Coffea*, and was so called by Linnæus and Aublet. In our stoves the species are grown in sandy loam and moor-earth, and may be increased by cuttings.

TETRANTHERA (Jacquin). A genus of evergreen shrubs and trees, natives of Australia, India, and Mexico, separated from the genus *Litsea* of Lambert and others. The flowers are enneandrous, and the genus ranges among the *Laurinæ*. The species require the ordinary stove treatment as well in growth as in propagation.

TETRATOMA (Herbst). A genus of coleopterous insects, belonging, according to Latreille, to the section *Heteromera* and family *Diaperidæ*, distinguished by having the body of an oblong-ovate form, with the tibiæ narrowed and without spines, the antennæ as long as the head and thorax, and terminated by a four-jointed club; the two posterior tarsi have only four joints, nevertheless it appears to us that this genus much more nearly approaches some of the *Necrophaga*, or rather fungivorous beetles, and especially to the genus *Mycetophagus*. The dissections of these two genera, given by Mr. Curtis in his British Entomology, fully confirm this relation. There are two British species of small size, *T. fungorum* being the type. They are found in fungi, and under the bark of trees.

TETRIX, (Latreille); **ACRYDIUM**, (Leach). A genus of small but curious orthopterous insects, belonging to the family of the locusts (*Locustidæ*), distinguished by having the hinder part of the head received beneath in a produced part of the prosternum, forming a kind of cravat; the lower lip is divided into four lobes, the tarsi have no pulvilli, the antennæ have only thirteen or fourteen joints, and the upper side of the prothorax is prolonged behind in the shape of a large scutellum, entirely covering, and occasionally extending considerably beyond, the extremity of the body; the clytra are minute, but the wings are large and folded up like a fan; the species are very small and obscurely coloured; they frequent warm grassy banks, and are occasionally very plentiful in such situations, as for instance, in one part of Battersea Fields, well known to collectors under the name of the "Acrydium Bank." The type is the *Acrydium subulatum*, Fabricius.

Tripetalocera ferruginea, figured in our plate ORTHOPTEROUS INSECTS, from Malabar, and described in the Zoological Journal, No. 20, is distinguished by the curious structure of the antennæ, which have only six joints, and by the compressed keel upon the back.

TETTIGONIA. A generic name employed in entomology for several very distinct groups of homopterous insects. Fabricius, followed by the German writers, gave this name to the musical cicadæ. Stephens and Curtis employ it for the frog-hopper (*Aphrophora spumaria* of Germar), whilst Latreille gives it to another group, having the head, when seen from above, of a triangular form, without being very much elongated or flattened, the eyes not incised by the margins of the head, and the ocelli situated between them, or laterally. In this confusion of

nomenclature (entirely resulting from the non-adoption of some fixed principle regulating the employment of long-established generic names, when it has been thought necessary to subdivide an old genus) it would perhaps be most advisable entirely to abandon the old name *Tettigonia*, and to give to the musical Cicadæ, or the Fabrician *Tettigonia*, the generic name of *Cicada* (as has already been done in the course of this work), to give to the frog-hopper the name of *Aphrophora* (see the article CECARIDÆ), and to call the Latreillian *Tettigonia* by the generic name of *Cicadella*.

TETYRA, (Fabricius); **SCUTELLERA**, (Lamarck), which see.

TEUCRIUM (Linnæus). A numerous genus of shrubs, under-shrubs, and herbs, the latter both annuals and perennials, the whole divided into six sections. The flowers are didynamous, and of course rank among the *Labiata*. Some of the species are ornamental and admitted into our hardy and greenhouse collections, and are all easy of propagation by seeds or cuttings. The English name is Germandia.

THALICTRUM (Linnæus). A genus of herbaceous perennials, mostly European, known in English lists as meadow rue. The flowers are polyandrous, and belong to *Ranunculaceæ*. They grow well in any soil in the open borders, and are easily increased by division.

THANASIMUS (Latreille). A genus of coleopterous insects, belonging to the family *Cleridæ*, having the antennæ gradually thickened, the maxillary palpi filiform, and the labial palpi securiform. The species are of moderate size, and from the peculiar character of their appearance and colours have obtained the specific names of *Formicarius*, *Mutillarius*, &c., from their resemblance to ants, *Mutilla*, &c. One species is found in this country, *T. formicarius*, which is occasionally met with in considerable numbers under the bark of old stumps, where it is probable that its larvæ feed upon the larvæ of the wood-boring *Anobia*, which frequent the same situations.

THAPSIA (Linnæus). An umbelliferous genus of European perennial herbs, formerly called *Laserpitium* by Desfontaines, and easily increased in the open border by seed.

THEA (Linnæus). This is the celebrated and useful Chinese tea plant. The flowers are monadelphous, and being nearly allied, are stationed among the *Camelliaceæ*. We have had two species (or varieties) of this valuable plant in our collections for nearly seventy years; but notwithstanding the long and constant intercourse our merchants have had with the Chinese empire since 1768, it is still uncertain whether the green and bohea sorts we have in our gardens be or be not the true plants whence the manufactured commodity is obtained; for it is quite feasible to suppose that the tea-plant, so long and so extensively domesticated in that country, must have broken into many varieties, and the one producing the greatest number of leaves, and being at the same time of most moderate growth, would be preferred to varieties of more exuberant character. However this may be, a plantation of tea, seen in the neighbourhood of the city of Canton, appeared to be neither the green nor bohea of our gardens, but an intermediate sort. It is quite certain that the different descriptions of the manufactured article, both in the Chinese and home markets, arise entirely from the time of gather-

ing the leaves, the mode of curing, or from the district whence they are brought. The earlier in the spring the first leaves are gathered the richer the quality, and the more valuable the article, whether cured green or black. The tea grown on the sloping side of a hill is superior to that gathered from the summit, and both these are superior to that produced in the rich valley; hence several sorts may be sent to market by the same grower. The different descriptions of teas, however, are the produce of different districts, one being famed for black, another for green teas; and it has been affirmed that all the various sorts are gathered from the same species of the genus; this circumstance, however, still remains undetermined.

THECLA (Fabricius). A genus of small butterflies, belonging to the family *Lycenidæ* (which see), known to collectors under the names of hair-streaks, from the slender lines of white colour with which the under surface of the wings are in general ornamented. The caterpillars are very much like wood-lice, and hence are called onisciform larvæ. There are five or six British species, the handsomest of which is the purple hair-streak (*Thecla quercus*), which flies about the highest branches of the oaks, upon which the caterpillar also feeds.

THELPHUSA (Latreille). A genus of crabs belonging to the family *Canceridæ*, having the carapax or shell of a cordate-truncate form, the tarsi furnished with spinous warts or dentated, the lateral antennæ composed of very few joints. Several species of this genus of crabs are known, all of which, contrary to the usual habit of the tribe, reside in fresh water, having even the power to remain for a considerable period out of the water. The *T. fluviatilis* was well known to the ancients; it is very common in Italy, being found in lakes and streams; it is also often found to be represented upon antique Greek medals. It is about two inches in diameter, and of a grey or buffish hue, differing when dead, very smooth above, except at the sides, which are covered with small transverse impressions. It is eaten by Greek monks, and forms, during Lent, one of the Italian fast dishes. Another species, *T. Indica*, was discovered on the coast of Coromandel, where it is called by the inhabitants *Tille Naudon*; and Colonel Sykes has given an account of another species, *T. cunicularis*, which he discovered in the Deccan or Dukhun as he writes the name. It is called *Kenkra* by the Mahrattas, and abounds along the Ghâts. Their burrows are found in all the valleys, and on the most elevated table lands, from 2000 to 5000 feet above the level of the sea. In the abundant rains of the south-west monsoon, they are seen in a state of great activity running over the surface, and frequenting the public roads in such numbers that instances are constantly occurring of their being crushed under the feet of horses and cattle, those of foot passengers, or the wheels of vehicles. During the months of extreme dryness, December, January, and February, they are rarely seen out of their holes. As they are met with of all sizes, it is probable that the reproductive process takes place without having recourse to migration to the seashore, as is related of some species of land crabs. Indeed nothing of the kind had been even observed by Colonel Sykes, or his friends and native servants. The celerity and ease with which the two fore claws are used make them efficient substitutes for hands, and its rapid lateral movements at pleasure to either side, as objects attracted its attention, were

very efficacious in enabling it to capture its prey, which appeared to consist of insects and animal matters of various kinds. This observation of Colonel Sykes (*Trans. Ent. Soc.* vol. i. p. 183) appears to have more weight, judging from the habits of the crabs in general, than the statement of Bishop Heber relative to the supposed food of these animals. "All the grass through the Deccan," observes this writer, "generally swarms with a small land crab, which burrows in the ground, and runs with considerable swiftness, even when encumbered with a bundle of food as big as itself; this food is grass or the green stalks of rice, and it is amusing to see the crabs sitting, as it were, upright to cut their hay with their sharp pincers, then waddling off with their sheaf to their holes as quickly as their sidelong pace will carry them."

THEOBROMA (Linnæus). A genus of South American trees, two of which are cultivated for the fruit, which, when manufactured, is the favourite repast chocolate. The flowers are polyadelphous, and the genus belongs to *Byttneriaceæ*. In our stoves they are grown in light compost, and are readily propagated by cuttings.

THEOPHRASTA (Linnæus). A genus of highly ornamental shrubs or small trees, having pentandrous flowers, and belonging to *Apocynææ*. Natives of Hispaniola, they require the warmest part of our stoves, and may be increased by cuttings rooted in sand.

THEREVA (Latreille). A genus of dipterous insects, placed by Leach in the family *Mydasiidæ*, but by Latreille in that of *Leptidæ*, having the wings not folded upon the body when at rest, and exhibiting many complete cells. The palpi are received, when at rest, in the oral cavity, and the antennæ terminate in a spindle-shaped mass, with a small articulated style at the tip. There are ten British species, the type being the *Bibio plebeia* of Fabricius. Some of the species are very common, being found in open parts of woods.

THLASPI (Dillenius). A genus of European weeds, called Shepherd's Purse; they belong to *Cruciferæ*, and are found everywhere.

THOMASIA (Gay). A genus of New Holland shrubs belonging to the fifth class of Linnæus, and to the order *Byttneriaceæ* of Jussieu. The genus was formerly called *Lasiopetalum*, and is best known in greenhouse collections by the old name.

THRIPS (Linnæus). A genus of minute but very curious insects, placed by Linnæus in the order *Hemiptera*, by Latreille in the *Homoptera*, but recently separated by Mr. Halliday as a distinct order under the name of *Thysanoptera*. The body is long, narrow, and sub-depressed, resembling that of a *Staphylinus*; the antennæ short and composed of eight joints, the terminal joint being unarmed by a seta; the four wings are of equal size and form, long and linear, deeply fringed with hairs on all sides, and laid horizontally upon the back; the tarsi are short and terminated by a vesicle instead of the ordinary ungues; the rostrum is described by Latreille as being small or scarcely distinct, but the mouth is not rostrate strictly speaking, but armed with mandibles and palpigerous maxillæ, and thus entirely differing from the other haustellate insects.

These insects are of exceedingly minute size, few exceeding a line (one-twelfth of an inch) in length; they are very active, seeming to leap rather than fly

when disturbed. At such times also they elevate the posterior extremity of the body like a *Staphylinus*, giving it various movements. They are found upon flowers and plants, and under the bark of trees. The different species of this genus are well known to gardeners from their attacks upon different trees, cucumbers, &c., their punctures upon the leaves giving them a dead appearance, curling them up at the sides, and appearing as soon as the least verdure is seen, at which time they are in the larva state, although some are perfect. The larvæ are long and of a faint yellow, and when fully grown are nearly the size which they attain in the winged state, which is very small. For some time after the insect attains the winged state, it retains nearly its original colour, but afterwards turns nearly black. They especially infest melons, cucumbers, vines, kidney-beans, &c., particularly attacking the blossoms; the marks which they produce being in patches, and deeply scalloped. They also attack the young leaves of peaches and nectarines as soon as they appear in the spring, which causes them to shrink up, and they also prey upon the bloom before it expands. They feed in the interior or fructification part, which weakens it materially, and causes the blossom-bud to fall off before it is formed into fruit (Major on the Insects injurious to Fruit Trees).

The student must consult Mr. Halliday's Memoirs upon these insects, published in the Entomological Magazine, where numerous species are described.

THROSCUS (Latreille). A genus of coleopterous insects, belonging to the section *Pentamera*, apparently forming the connecting link between the families *Elateridæ* (having the elongated form and the produced prosternum of that family), and the *Byrrhidae* or *Dermestoidæ*, having the antennæ terminated by a three-jointed club. The species are of a small size, and are found in sand-pits or upon trees. The type is the *Elater dermestoides*, Linnæus, of a brown colour.

THRUSH (*Turdus*, perhaps rather *Turdidæ*, the thrush family, or *Merulidæ*, the blackbird family), a family of dentirostral birds, of the order *Passeres*, which, after all the reductions that have been made, is still both numerous and interesting. Thrushes, or birds bearing considerable resemblance to thrushes, are found in almost every part of the world. Those which inhabit the high latitudes, and places which are otherwise very seasonal in their character, are in general migratory; and those which inhabit places of more mild and uniform character are in general stationary; but a good deal depends on the particular kind of places which the birds haunt. Thus, a bird whose habit it is to reside in the copses, gardens, and hedge rows of the warm and cultivated districts of a country, can find food all the year round; while in the wilds a bird finds no food in the winter.

Among birds which are so widely spread over the world, there must of course be many differences of habit, to suit them to the different localities in which they are placed, and the different purposes which they have to answer in the grand system of nature. It is therefore not possible to give any description of the manners of a thrush that will apply to all thrushes, even in the most restricted view that we can take of the family. Their use in nature must obviously be very general; for all the children of nature, and all their organs and adaptations, are made for uses; and then, as the use varies, the structure must vary

along with it, so as that the two may be always in harmony.

Thrushes have been celebrated birds from very remote antiquity, not only on account of their songs, but of their flesh. A distinction is made among them of merles and thrushes, the former having the colour entire, and the latter broken and mottled. The blackbird and the common song-thrush are instances of these, but the distinction is not a very important one. When we mention that the number of species that have been described amounts, exclusive of doubtful ones, to between 140 and 150, it will readily be understood that a minute description of them all would be incompatible with the character of the present work. Nor is it necessary, for there is a considerable resemblance among them, varying chiefly with the different characters of the places they inhabit.

The other genus which they resemble most are the shrikes (see *LANIUS*); but they are not so exclusively animal in their feeding, many of them subsisting upon wild berries in the autumn and winter, though they prefer small animals, especially mollusca and worms, when these can be obtained.

The generic characters are: the bill of middle size, sharp edged, compressed, and recurved at the tip, with a notch near the point, and a few loose hairs over the base; the nostrils oval, lateral, half concealed by membrane; middle toe not so long as the tarsus, and the outer toes joined to it at the base. We can afford to give only an outline of a few of the species.

MISSAL THRUSH (*T. viscivorus*). The largest of the European species, weighing about five ounces, and measuring eleven inches in length, and between sixteen and seventeen in the stretch of the wings. The general colour greyish on the upper part, and yellowish-white on the under, mottled with dusky spots, and with some white on the exterior feathers of the tail. The female paler on the upper part, and with a tinge of russet on the under. The colours are not very constant, however; but vary in different habitats, and even in different individuals in the same. It is common in the middle and cold parts of Europe, from the latter of which it in general migrates in the winter. It is a woodland bird, but it prefers the woods of low and fertile places. In Britain it is more abundant in the south than the north. The song of the male is loud and clear, and far from unpleasant; and it is one of the first songs of the year, being begun as early as January if the weather is genial; and if the song is once begun, the bird goes on despite the storm, even though one should ensue. The call-note, or usual cry of the bird, is not a song, but a harsh and grating scream. The nest is formed about March, rather in copses than in the wild and extensive woods, and in an orchard in preference to any other place. The external part is made of sticks, coarse vegetable fibres, moss, and an admixture of earth; and lined with finer vegetable matters and with wool. The eggs rarely exceed four or five; they are of a flesh-colour with dark rusty spots. The male continues his song during the incubation, and also shares in that labour; but when the young make their appearance, the providing of food for them leaves no time for singing. If the season is favourable there is a second brood, in providing for which contributions are levied on the small succulent fruits of the garden, whereas the brood of the spring are fed upon snails, slugs, and other small animals which

are garden pests. If any casualty befalls the female, the male immediately renews his song; and if he should not be able to attract another, he continues the whole season over, so that the song of bereavement, which has been attributed to the nightingale and the turtle by the poets, is really by the missel thrush. With him, however, it is no song of lamentation; for in nature there is no remembrance of sorrow, it is a song of invitation to another; and if that other is not found till the very hot weather, then this bird occasionally bursts violently into song, at the time when most birds begin to be silent.

These thrushes, and indeed almost all thrushes, are unsocial birds, and very apt to quarrel and fight upon matters both of occupation and of gallantry. They are said, however, to be of some use to other birds in the case of a predatory foe appearing upon the breeding grounds. The male thrush, being a vigilant watchman, keeps sounding the alarm until all the finches and other small birds are mustered in a state of excitement; and then he leads them against the enemy, who, though a fierce bird, is seldom much of a soldier, and so he is beaten off, and the victorious birds return to their domestic labours. In winter and early spring the missel thrush generally feeds on the leaves of the miseltoe and the ivy, and it is from feeding on the former that the bird gets the name of missel.

|| THE SONG THRUSH (*T. musicus*). This is "the thrush" by way of eminence, at least in England in modern times. In Scotland it is the *navis*. It is considerably smaller than the missel thrush. The length is about nine inches; the extent of the wings about thirteen and a half inches; and the weight three ounces; the ground colour above is brownish grey, and that below whitish red, with many spots of dusky and rust colour; there is also a yellowish tint on the wing-coverts next the body; but the colour is, upon the whole, nearly the same as that of the missel thrush, only the small size readily distinguishes them; and this one has an air of greater hardihood than the other. It is also much more common, found in more bleak and upland places, and it ranges farther into the north on the continent of Europe.

In Britain the song thrush is, in great part of its motions, a resident bird, and one which merely comes nearer houses, and passes into the warmer districts, when the winter is very severe; but on the continent it is more migratory, and moves in great flocks on the autumnal migration. There is a particular summer attraction for it in the north of Europe. Great part of the surface there, beyond the tall forests of pines, is covered with extensive brakes of juniper, the berries of which are ripe in the summer, as they come to their size in the preceding year, and have only to ripen during the last year they are on the bushes. These bushes are close, and, from the spiny nature of the leaves, they are not very pleasant for birds of prey to beat; so they form a close and safe cover for the nests of the thrushes, at the same time that the leaves afford an abundant supply of food both to the birds and to their young. When this supply fails them, or rather, when it begins to be buried up by the snow, which comes suddenly and in great quantity, the birds are driven southward, and they proceed to more genial climates. The north of Russia, rather than that of Scandinavia, or the flats on which the junipers grow, are far more extensive. Hence the autumnal migration of thrushes

is more to the eastward of the Baltic than across that sea. They, however, distribute themselves along the southern shores of the Baltic; and it has been stated that, in the city of Dantzic alone, little short of two hundred thousand have been captured and sold for the table in the course of one season. They occur in vast numbers upon the eastern migration, and find their way there not only to Greece and to Italy, but also, as is said, to Egypt, in which latter they arrive in October, and depart again in March. The birds which take these long journeys have not of course more than one brood in the year, and that brood is reared in the most northerly part of their range.

With us they may be partially migrant, and indeed there seem to be some varieties which are wholly so, for the thrushes which are the greatest favourites with the bird-catchers, as song birds, are not seen before March, or after September. Those which do not make long journeys, or pass into places where the summer is short, breed twice, or even in some instances three times, in the course of the season. The nest is a compact structure, formed externally of moss and fibres, and strengthened with an admixture of mud. It is generally in the corner of a hedge or bush, or of a thick tree, but seldom at any considerable elevation above the surface of the ground. The eggs vary from three to six, being more numerous when the birds breed only once in the year, and have their broods later in the season. The ground colour of the eggs is pale greenish blue, and they are mottled with small spots of rust-colour and black, most abundant toward the larger ends. Every one knows the song of the thrush. It is very sweet, and has considerable compass. In a state of wild nature thrushes are not without a pugnacious tendency; and, even in confinement, they menace with their bills if annoyed. They have, however, a good deal of what is usually called intelligence, and can be made to repeat musical airs, or in some instances to articulate words. When the family are called *Thrushes*, this is the bird which may be considered the type, that is, the one from which the principal characters of the family are taken; but when they are called *Merles*, the one next to be noticed is the typical bird.

THE BLACKBIRD (*T. merula*). The blackbird is larger than the song thrush, and nearly as long as the missel, but not so stout and heavy a bird. The general colour of the plumage is black; and the bill, the feet, and a circle round the eye, are tawny yellow. The bird does not, however, need any particular description, as it is one which is well known to every body.

◀ The blackbird is very common in all the temperate parts of Europe, and also of Asia, and it is by no means so discursive in its habits as the song thrush, though it is a migrant in the east of Europe and in Asia. Blackbirds are even more solitary in their habits than thrushes, and, even where they are migratory, they do not collect in such numbers in the autumn. In the richer parts of Britain, where they may be considered as stationary, they are always solitary except in the breeding season. They are also very wary birds, and keep themselves much out of harm's way, although they are very familiar, that is, court the neighbourhood of houses, and appear in gardens, even in the open places of cities, in the cold season:

They belong to that class of birds—a class in habit, though it consists of many orders, according to

the arrangements of naturalists, which increase rather than diminish as the country is more thickly peopled and better cultivated. In no places are they more abundant than in the market gardens, where vegetables and fruits are grown to supply the consumption of populous towns and cities. In the rich grounds on the Middlesex side of the Thames, from Westminster upwards, as far as the market-gardens are continued, blackbirds are very numerous. They are at the same time highly useful in clearing the ground of snails and slugs, which are among the worst enemies of some parts of the growth and produce, and also among the most difficult to be got rid of by human means. In walking along the green lanes among the gardens alluded to, the numbers of the blackbirds, and the activity of their labours, are a very pleasing sight; and one might readily imagine (though it is of course a mere matter of imagination) that the birds feel that they are as useful as the human labourers who are at work in the same grounds. They are familiarised to all the ordinary sights and sounds, caring little for the scarecrows which are set up for intimidating other birds; and although no bird is very fond of the report of a musket, blackbirds appear to be less alarmed by it than most others.

The song of the blackbirds, which, although there is not very much music in it, is soft and mellow, begins early in the spring, not quite so early as the missel thrush, but not very long afterwards. They breed once, twice, or three times in the season, according to the nature of the situation. In cold parts of the country, where the summer is short, they breed only once, and their song does not begin till the season is considerably advanced; and when once it ceases it is not again renewed the same year. Where they breed twice or thrice in the year, the song is heard, with little intermission, from first to last; for although the male does not sing after the young are hatched, yet the hatches not being at exactly the same time in all the pairs, one or other is in song from the time of the first impulse in the spring to the development of the last brood in the autumn.

The external part of the nest consists of moss and lichen, worked up with mud, and the structure lined with fine vegetable fibres and feathers. Both parent birds labour at the construction of the nest, and with so much assiduity that, though the fabric is rather an elaborate one, it is finished in about a week. The eggs vary from four to six, and are of a greenish blue colour, with obscure though numerous markings of rust-colour. The male takes a share in the incubation, though not quite so large a share as some other birds. The nests are usually in close concealment, and still further concealed by their substance resembling that of the mossy trunks against which they are placed; they do not, however, avoid places which are frequented by human beings, for a nest may be often seen in a shrub close by a summer-house in which there is company every day, and the bird will sit with perfect unconcern, within a few feet of those who are in the house, if they do not actually meddle with her or her eggs. The more woodland ones, in situations where there is no cover for them in the gardens, are a little more timid, but their nests are generally so placed that they are not very likely to be seen; and the birds repair to the nest and quit it so warily that they do not betray the exact place where it is situated; in fact, it is always so placed

that the bird can escape to a considerable distance, under the cover of the sprays, before it makes its appearance, and then, as it doubles after it is seen, there is no retracing its passage to the nest. The young blackbirds are hearty feeders, and thus the parent birds have to capture a vast number of worms and all sorts of larvae for their support—the snails and slugs being generally down at the time when the birds have their broods, more especially their first one for the season. In winter the blackbirds are very partial to the cover of evergreen shrubs, partly, no doubt, because those afford more shelter and concealment than the leafless sprays of deciduous trees and bushes, and partly also because food for them is found in the shelter of these plants, when there is none where the earth is freely exposed to the atmosphere.

FIELDFARE (*T. pilaris*). This is a slender-bodied and well-winged bird, and as such of a much more migrant and discursive character than any of the species hitherto noticed. It measures about ten inches in length and sixteen in the stretch of the wings, and weighs about four ounces; the upper plumage is brown red, the under clouded with dusky, with the tail feathers black, except the tips of the outer ones, which are white, and the top of the head and the rump are of a hoary or whitish colour. The plumage is, however, subject to considerable varieties.

It appears as a regular winter visitant in Britain, and in all the middle and south of Europe, and in Egypt; and it abounds in Asia, where also it is a seasonal migrant, coming southward in the autumn and retiring northward in the spring. In Britain it generally appears about the end of September, but sooner or later according to the character of the season. It is not the season with us, however, but the season in those places from which they come, that regulates the time of their appearance and the numbers in which they appear; and thus they often appear early and in abundance when the weather is serene and warm, and do not come when it is turbulent and broken. Their coming in numbers is, however, always a sign that the winter has set in, early and with severity, in the north; and when that is the case we generally find that our turn of it is sure to come. Thus the early appearance of fieldfares, and indeed of all birds which summer in the north, may be taken as a certain omen of a severe winter. They always come in little flocks, which may be seen on the wing beating about for those grounds which are most suitable for them. They arrive much more early in the northern parts of the country than in the southern, and they seldom reach the south of Europe before the end of autumn. In very severe winter storms they are often driven upon our shores in great numbers, and in a very exhausted state. This happens when the storm comes from the north-east, and we may suppose that they are beaten to leeward on their flight to a more southerly part of the continent. In most parts of Britain they are only birds of passage, at least if the winter is severe, and they are more moveable with the storm than almost any other birds; they are also social birds in the winter, for though they range the moors and other pastures singly, they collect in flocks at night, in case of alarm, or of severe weather forcing them to change their ground. They roost for the night on the ground squatting in the herbage, but they assemble on trees; and if there are trees convenient in the neighbour-

hood, they make their evening assemblage there before they depart to the places where they are to repose. In countries where they are abundant, and there is plenty of food for them, their flesh is held in high estimation, as indeed is the case with that of all the thrushes.

The breeding place is not positively ascertained, but it is in more northerly latitudes than the birds frequent in the winter; and many of the European ones do breed in the north of Russia and Scandinavia; but it is supposed also that a considerable number, especially of those that winter in Italy or in Africa, breed to the south of the Baltic. The nest is in trees or bushes, and the eggs from four to six in number, of a sea-green colour, mottled with rusty brown.

RED-WING (*T. iliacus*). This species migrates about the same time as the fieldfare, and is often found in company with it, but they are easily discriminated; and this one is more apt to be confounded with the common thrush than with the other. It is a smaller bird, however, being only about eight inches long, and two ounces and a quarter in weight. The upper parts are greyish, the under whitish, and the whole marked with dusky spots; the under sides of the wings and the body under them are rusty red, from which the bird gets its name; its colours are altogether more clear and bright than those of the song thrush, and its bill is blacker.

The red-wing is a northern bird in the breeding season, though perhaps not so much so as the fieldfare. It does not breed with us, at least the fact of its doing so is not very well ascertained; but it does breed in some places, south of the Baltic, upon the continent; and it is not improbable that they may breed in some parts of Britain, although the nest has not been found, or the song of the male heard. With us they have a sort of shrilly cry, between a squeak and a whistle; but in the northern parts of the continent, where their breeding has been well ascertained, the male has an agreeable song. They breed on the bleak and bushy grounds in Holland and Germany, and generally in places where there are wild berries; but their summer food consists of insects and their larvæ and worms. When their wild food fails in the autumn, and, indeed, whether it fail or not, they are apt to visit the orchards and gardens, and levy contributions on the smaller fruits; but, as is the case with all birds which are insectivorous in the breeding season, the ravages that they commit in the latter part of the season are more than compensated by the services which they perform in the spring.

The red-wing, though it resembles the song thrush in the appearance, and also in some of its habits, is not so much a woodland bird. The nest is generally in cover of some kind or other, but it is in the cover of a hedge or bush, rather than in that of a tall tree. The breeding season, at least in the more southerly places, where the birds breed, is from April to June inclusive; and in the southerly places there are usually two broods within this period. The eggs, as in most of the others, vary from four to six, of a pale greenish-blue with dusky brown spots. This species is subject to very considerable differences of colour; and some individuals have been met with almost entirely white when it comes as an autumnal migrant; the red-wing, like the fieldfare, prefers the open fields and the commons where there are hedges and brakes to the thick cover of the woods.

RING-THRUSH (*T. torquatus*). This species, which

is also called the ring-ouzel, the blackbird being called the black-ouzel, resembles the blackbird more than it does the speckled thrushes; but its haunts are, in some respects, the very opposite. It is dusky black, with a white collar forming a crescent on the upper part of the breast; its length is eleven inches, the extent of its wings seventeen, and its weight four ounces. It is well formed for flight, being thick and firm at the shoulders, and tapering to the rear, and the flying feathers, both of the wings and the tail, are strong and elastic. It is a migrant bird, but its migration is a compound one, regulated both by difference of ground and difference of latitude; and sometimes the one of these, and sometimes the other, predominates in bringing about the general result. It appears on the low grounds in the temperate parts of Europe both in the spring and in the autumn. In the summer they disperse over the upland tracts, not the lofty mountains, but the secondary hills, where they are most partial to wild and rocky places.

In Britain, the chief place for their spring appearance is the middle of the south coast, from which they diverge along the heights, being rarely if ever found in the great valleys or the places which are the favourite haunts of the warblers. The nest is in a bush or tuft, or on the ledge of a rock where there is an overhanging canopy either of rock or of vegetation. The male sings when in the wilds, but the song is not a loud one, though rather sweet and agreeable. It is usually delivered as the bird stands perched on the point of a rock, or the top of some elevated stone. Ground insects appear to be their chief food in the breeding season, and such insects are especially abundant in those places which the birds frequent at that season. The nest is formed of moss and lichen, of which the rocky places furnish an abundant supply; these are consolidated with mud, and the whole lined with fine vegetable fibres; the eggs are from four to six, but very rarely the latter number; they resemble those of the blackbird; but the ground colour inclines more to green, and the mottlings are more definite. There is one rather formidable enemy of which the ring-thrush stands in danger on its rocky pastures, and that is the martin, which spends the summer upon nearly the same grounds.

The birds are usually on the low grounds again about the month of September; but they do not remain in Britain all the winter; and on the continent they also retire to the south at that season.

SOLITARY THRUSH (*T. solitarius*). This is also called the blue thrush from its colour. It is a European species; but we are not aware that any specimen of it has hitherto occurred in Britain, even as a straggler. Indeed it has but little tendency to migrate; and its migration, in so far as it does shift its ground with the seasons, is not in latitude. It inhabits the mountainous parts of the south of Europe; and mountain birds seldom have much tendency to migrate, more particularly in countries not in very high latitudes. In such places they have only to move up the hill in summer, and down in the winter; and a few thousand feet of change in this way is equivalent to a considerable range in latitude. The general colour is blue, with grey margins to the feathers; the bill and arch of the eyes yellow; the size rather smaller than that of the common blackbird, but the habits a good deal the same; the bird is shy and wary, and builds its nest in the most difficult parts of

the mountain rocks ; the eggs are of a paler tint in the ground than those of most of the thrushes ; they are sometimes so obscurely marked as to appear entirely white, and at other times they have obscure dusky mottlings. Its song is remarkably loud and clear, and therefore it is sought after ; but it is delicate in confinement, and is rather fastidious in the delivery of its song.

Those which have been enumerated are the principal thrushes of Europe ; but there are many other birds which have been called thrushes, among which the dippers, the porters, and in other parts of the world the ant-eaters, have been included. America is, as one might readily infer from its woods, its waters, and its great abundance of insects and other small animals, a very favourable country for thrushes. Our limits will admit of a notice of one or two of the leading ones only.

MOCKING THRUSH (*T. polyglottus*). This, as its name implies, is a bird of many tongues, and from the readiness with which it acquires and uses them, it is one of the most remarkable of the feathered race. It is found both in North America and in the West Indies, and it is a migrant ; but it has less and less of the migratory habit in proportion as it inhabits regions farther to the south. Indeed, it is only in the most northerly part of its range, and during winters of more than usual severity, that it wholly leaves the same locality at any season of the year. The berries of the cedars (junipers) and other evergreens which grow so luxuriantly in the swamps of the southern parts of the American states, together with the berries of many of the bushes, both evergreen and deciduous, which cover the less humid wastes with one continuous brush of underwood for many miles, furnish these birds with an ample supply of food even in the most severe weather, so that covering up by the snow is the only thing which can completely shut up the stores from the bird ; and in the close evergreens, on the swamps especially, this can but rarely happen. Accordingly, the song of this bird begins in the southern states as early as February, even in the warmest winters ; though it is much later in the northern states, not before April, or even May, in places very far north.

The nesting time, of course, varies as much, though the nest is not begun, even in the south, before the first of April ; and in the north, it is four or six months later. A close and solitary bush or thicket is preferred to any portion of the continuous wood, and the bird does not hesitate to build in the close vicinity of human habitations, if the best place for its nest should happen to be there. This nest is constructed with a good deal of care, always of vegetable matters, and those matters vary of course with the localities, as is the case in the nests of all birds which nestle over a wide range of country. The eggs are rarely more than four, and the brood are hatched in two weeks, so that there is time for a second brood over nearly the whole range of latitude in which the bird is to be found ; and, as is pretty generally the case with birds which have two broods in close succession, the destruction of the second, if it should occur, is followed by the production of a third. The defence of the nest cannot be stated in any words but those of Wilson : " During the period of incubation, neither cat, dog, animal, or man can approach the nest without being attacked. The cats, in particular, are persecuted whenever they make

their appearance, till they are obliged to retreat ; but the whole of his vengeance is most particularly directed against that mortal enemy of his eggs and young, the black snake. Whenever the insidious approaches of the reptile are discovered, the male darts upon it with the rapidity of an arrow, dexterously avoiding its bite, and striking it violently and incessantly about the head, where it is very vulnerable. The snake even becomes sensible of its danger, and seeks to escape ; but the intrepid defender of his young redoubles his exertions, and, unless his antagonist be of great magnitude, often succeeds in destroying him. All its pretended powers of fascination avail it nothing against the vengeance of this noble bird. As the snake's strength begins to flag, the mocking bird seizes and lifts it up partly from the ground, beating it with his wings ; and when the business is completed, he returns to the repository of his young, mounts the summit of the bush, and pours out a torrent of song in token of victory."

This gallant and successful defence of the nest against foes which destroy so very many birds, and birds of apparently far greater powers than the mocking bird, would be a recommendation, though the bird had no other. But the air, the action, and the music of the bird, all tend powerfully to recommend it—" The ease, elegance, and rapidity of his movements, the animation of his eye, and the intelligence he displays in listening and laying up lessons from almost every other species of the feathered creation within his hearing, are really surprising, and mark the peculiarity of his genius. To those qualities we may add that of a voice full, strong, and musical, and capable of almost every modulation, from the clear mellow tones of the wood thrush to the savage scream of the bold eagle. In measure and accent he faithfully follows his originals—in force and sweetness of expression he greatly improves upon them. In his native groves, mounted on the top of a tall bush or half-grown tree, in the dawn of a dewy morning, while the woods are already vocal with a multitude of warblers, his admirable song rises pre-eminent over every competitor. The ear can listen to his music alone, to which that of all the others seems a mere accompaniment. Neither is this strain altogether imitative. His own native notes, which are easily distinguishable by such as are well acquainted with those of our various song birds, are bold and full, and varied seemingly beyond all limits. They consist of short expressions of two, three, or, at the most, five or six syllables, generally interspersed with imitations, and all of them uttered with great emphasis and rapidity, and continued, with undiminished ardour, for half an hour or an hour at a time. His expanded wings and tail glistening with white, and the buoyant gaiety of his action, arresting the eye, as his song irresistibly does the ear, he sweeps round with enthusiastic ecstasy—he mounts and descends as his song swells or dies away—and, as my friend Mr. Bertram expresses it, he bounds aloft with the celerity of an arrow, as if to recover or recal his very soul, expired in the last elevated strain." While thus exerting himself, a bystander destitute of sight would suppose that the whole feathered race had assembled together on a trial of skill, each striving to produce his utmost effect, so perfect are the imitations. He many times deceives the sportsman, and sends him in search of birds which are not

perhaps within reach of him, but whose notes he exactly imitates. Even birds themselves are frequently imposed on by his admirable music, and are decoyed by the fancied calls of their mates, or dive with precipitation, into the depth of thickets, at the scream of what they suppose to be the sparrow-hawk." "In his domesticated state, when he commences his career of song, it is impossible to stand by uninterested. He whistles for the dog; Cæsar starts up, wags his tail, and runs to meet his master. He squeaks out like a hurt chicken, and the hen hurries about, with hanging wings and bristled feathers, clucking to protect its injured brood. The barking of the dog, the mewing of the cat, the creaking of a passing wheelbarrow, follow with great truth and rapidity. He repeats the tune taught him by his master, though of considerable length, fully and faithfully. He runs over the quaverings of the canary, and the clear whistling of the Virginia nightingale, or red bird, with such superior execution and effect, that the mortified songsters feel their own inferiority, and become altogether silent, while he seems to triumph in their defeat by redoubling his exertions."

The bird is not only thus varied, superior, and free in the performance of his music during the day, but, when the proper circumstances stimulate him to the task (or rather the pleasure), he is to the full as ready to pour his song in the ear of night—not that he sings darkly, or "in shadiest covert hid," but he is as vigilant in the night as the day; and the instant that the rising moon begins to make its appearance, the bird breaks forth into song; and he is perhaps the only feathered thing in the woods that specially welcomes the queen of heaven with a song. He does this in domestication as well as in a state of nature; for, if his cage is so placed as that he even sees the rising moon, he begins to sing to it the moment that it makes its appearance. These birds are of course in great request among the keepers of cage-birds; and they can not only be reared from the nest, but they will breed in confinement—only, the breeding of them is attended with a very considerable degree of trouble, though they appear to be much more hardy birds than the finer species of the warblers.

It appears that this interesting thrush, which is not persecuted like some others, is becoming less numerous, and more of a summer visitant in the central states of the American union, in proportion as those states become more thickly peopled and more extensively cultivated. This does not seem to arise from any dislike which the birds have to the neighbourhood of man; for, as has been noticed, they will build in the immediate vicinity of houses. There seems to be some change of the climate, a hotter summer and colder winter probably, and a less productive state of the country on the average of the year. Something of the same kind is found in the inferiority of the crops; and it would not be difficult to find an adequate cause, were that not foreign to our subject.

The mocking thrush is about nine inches and a half long, and thirteen inches in the extent of the wings; but Wilson says that the birds of the second brood are smaller, that is, continue smaller in their maturity than the birds of the first brood. The upper parts are clear light grey immediately after the moult, but change to brownish ash colour; the quill and

tail-feathers are black; the first and second rows of the wing-coverts have white tips; in some males the coverts of all the primaries are white, and in others they are brown; the bases of some of the primaries are white as far as the coverts extend; the tail is wedge-shaped at its termination, and has the lateral feathers white, and white tips to all the rest except the two middle ones; the chin is white; the cheeks, sides of the neck, and all the under parts, brownish white; the bill black above and whitish on the under part; the legs and feet black, and stoutly made. The young birds have the under part spotted; but in the old ones the colour, though differing in different individuals, is entire. There is very little external distinction between the male bird and the female when they are mature.

THE CAT BIRD (*T. lvidua*). This is another American species, and an interesting one as well as the mocking bird, though its interest is of a very different character. It is a summer migrant, and moves about the same time as the mocking bird, but it is much more common, and is on the increase on the cultivated grounds, while the numbers of the other are diminishing. They winter, in the greater part of their numbers at least, in the southern parts of the States, and very soon after the dead of the year they are in motion. In Georgia they make their appearance in spring, and are gradually later and later, as the places to which they come are more northerly, till they reach the northern states, about the middle or the end of May. After their arrival they soon begin the labours of the year, the nest being placed in bushes, thickets, and trees, but not very carefully concealed. It is formed externally with coarse vegetable matters, and lined with finer fibres. The eggs are four, or sometimes five, of a greenish blue, without spots; and there are generally two, and sometimes three, hatches in the course of the season.

The cat-bird is nine inches in length; the upper parts are dark slate-black, and the under parts rather a paler shade of the same colour; the vent-feathers and under coverts of the tail are very dark red; the tail-feathers, the crown of the head, and the bill, are deep black.

The reason why this species gets the vernacular name of "cat-bird" is not any resemblance which the bird has to a cat either in its appearance or its habits, but wholly on account of the sound of its cry. "In spring and summer," says Wilson, "on approaching thickets of brambles, the first salutation you receive is from a cat-bird; and a stranger, unacquainted with its note, would instantly conclude that some migrant orphan kitten had got bewildered among the briars, and wanted assistance, so exactly does the call of the bird resemble the cry of that animal. Unsuspicious, and extremely familiar, he seems less apprehensive of man than almost any other of our summer visitants; for, whether in the woods or in the garden, where he frequently builds his nest, he seldom allows you to pass without approaching to pay his respects in his usual way." This bird is very common in most parts of the United States, so much so, that there is hardly a bush or thicket, or close array of small trees in a garden or orchard, which is without its cat-birds. They follow the steps of civilisation, for there are no cat-birds observable in the western settlements; when these are first taken possession of all is wilderness; but when they have been brought to even a mode-

rate state of culture, the birds are sure to make their appearance. They are about the least suspicious of all birds, and will allow very considerable liberties to be taken with their nests without deserting them. Some of the eggs may be taken out, or the nest itself may be shifted to a new situation, and yet, if it is placed so that she can see it, the female will return to her incubation as if nothing had happened; whereas, if the half of this liberty were taken with the nests of most birds, they would desert them. Wilson tried whether they would carry their indifference to circumstances to a greater length than this. He put two half-fledged young of one nest into another nest, in which the female was sitting upon five eggs, to see whether she would sit while the intruders were there; but she ejected them from the nest, and resumed her duty. They were not injured by their fall, and the male bird fed them with great attention.

Notwithstanding the obvious connection that there is between these birds and cultivation—for there is no animal that follows the progress of culture but what is in some way useful to the cultivator, whether he may happen to be aware of its use or not—notwithstanding this, the cat-bird is one of those species which meet with no protection, or even with cold and passive neglect; for it is one which the people of the States eagerly destroy, without being able to give any reason for their proceeding, or indeed knowing anything about the matter. It does not appear that this ignorant persecution has the smallest influence upon the number of the birds; for, in spite of it, they are multiplying in all parts of the country, while many of the races which do not meet with the same annoyance are diminishing in numbers. It is true that the birds are great plunderers of the produce of the gardens, and always ready to take the earliest and the best. This is plain and palpable; and the good which the birds may do, as a set-off against these depredations, is by no means so apparent. It is even so with our conduct towards mankind. He who takes to the amount of more than twenty shillings in a dwelling-house is a thief, and in peril of the merited gallows; but he who has prevented thousands of pounds from going to the comfort of dwelling-houses, by standing, in one of the many ways in which people can so stand between his fellow creatures and the honest earning of their bread, may, if he is rich, be the very best man in a country.

The cat-bird suffers not a little from the snakes, which are so abundant in many parts of America. The nest is in general near the ground, and the snakes steal upon it and devour the contents. If the male bird sees the snake, however, he instantly gives battle; and, though he is not perhaps so ardent and determined a warrior as the mocking bird, he is very often victorious. Considering the rapidity with which poisonous snakes start from their coil, and the certainty with which they strike, it is astonishing how dexterously these birds avoid the blow in their combats. We believe, however, that it is only during the breeding season that the valour of the birds is wound up to this pitch; and the boldness and certainty with which birds of naturally timid disposition and harmless manners beat off, without any formidable arms, animals stronger than themselves, and armed expressly for destruction, shows how much mere energy can triumph over the most formidable mechanical opposition.

WOOD THRUSH (*T. melodus*). This is another American species, partially migratory like the two former, and nearly at the same seasons, but its appearance and locality are different. Both of the preceding ones would be blackbirds or merles, if we were to make the distinction pointed out by our typical birds; and this one would be a thrush, as it has the under part mottled like our song thrush. This is the song thrush of the American forests, and it is really much more of a forest bird than those which resemble the blackbirds; for they are rather bush birds or brake birds.

This species is smaller than our thrushes, though some of the American ones are still smaller. The length is eight inches, and the stretch of the wings thirteen. The bill is an inch long, bent and notched at the tip of the upper mandible, and brown save the base of the lower mandible, and that is flesh-coloured. The legs, which are long, are also flesh-coloured, but a shade lighter. All the upper parts are tawny brown, passing into reddish brown on the top of the head, and into olive ash colour on the rump and tail; the chin, throat, and breast white, the last with a tinge of buff colour, and finely mottled with dusky black, running in chains of spots from the gape, which chains intersect each other on the breast and belly. The lower belly and the vent feathers are pure white; the eyes large, clear, and black, and surrounded by a white circle, and an iris of chocolate red round the black pupil; the gape yellow. The male and female birds are very like each other in appearance.

These birds range very extensively along the continent of North America, being found all the way from the Floridas to Canada, and even to Hudson's Bay. In the extreme north they are wholly migratory, and in the south they are stationary, and the characters are of course mixed in the middle latitudes. These thrushes are shy and retiring birds, not often quitting the woods, and are only solitary or in pairs. The male bird is a pleasant songster, and continues to sing in those gloomy states of the weather when most other birds are mute. The song is begun early in the morning, ceases in the heat of the day, and is resumed again in the evening. The song is often delivered from an elevated perch, the summit of the tallest tree in the grove, and two of the birds so perched will often sing with strenuous rivalry against each other.

The nest, as in most of the thrushes, is usually situated near the ground, in a low and sheltered situation, by the bank of a small stream where the herbage is luxuriant; and the nest is concealed in a thick bush. Withered leaves form the first or basal layer of the nest, and above these there is a frame-work of small twigs and stems, well plastered with mud, and last of all a lining of fine vegetable fibres. The eggs are four in number, or more rarely five, of a pale bluish colour without any mottlings. Berries in the season when they are abundant, and larvae and beetles in the summer, appear to be the principal food of these birds.

THE ROBIN (*T. migratorius*). The epithet which has been given as the specific name of this bird shows how unwise it is to name any bird after a particular habit; for it is one of the least migratory of all the thrushes of America, at least in so far as migration in latitude is concerned. Its migration is towards the coast in the winter, and back into the interior in the summer, and even this applies but to a very small

Condor

Bearded Vulture.

portion of the length of the United States ; for, except in the south, numbers of the birds remain in the coast country to breed. All along the line, however, they collect toward the shores in great numbers when the winter is severe.

The length of the bird is about nine inches and a half ; the bill shorter in proportion than that of the wood thrush, and yellow ; and the feet dark brown, with very strong black claws. The head, neck behind, and tail, are black ; and the intermediate portion of the upper part ash colour ; the wings black, margined with ash ; the inner tips of the two lateral tail feathers white. There are three small spots of white near the eyes, and the throat, which is black in the ground colour, is streaked with white. The upper part of the breast is black, and the remainder of it, as far as the thighs, bright orange red. The last is the part of the marking from which the bird gets the popular name of the robin. Behind this reddish colour the under part is white, varied with longitudinal streaks of dusky ash colour. The females have all the colours paler, especially the red on the breast. The nest is built in trees and bushes ; the external part, as in the others, plastered with mud. The eggs are generally five, and of a fine aquamarine green, without any markings. In summer the birds feed chiefly upon insects and worms, and in winter upon different kinds of berries, especially those of the poke (*phytolacca*), a plant the berries of which have a rich carmine-red juice, and the young shoots are eaten as asparagus ; but the whole of the plant has very active medicinal qualities, which, it is said, the berries communicate to the flesh of the birds that feed upon them. Otherwise the flesh of these birds is held in high estimation, and they may be had in very great numbers ; for they extend over the whole breadth of North America, as well as the length, and congregate upon the low grounds when the weather is severe.

RUEY-COLOURED THRUSH (*T. rufus*). This is the largest of all the American thrushes, being nearly a foot in length ; but it is not proportionally so well winged as most of the others, the extent of the wings being only about an inch and a half more than the length. The upper parts are bright reddish brown, with two bars of white, margined with black, on the wings ; and the tips and inner webs of the quills dusky. The tail is very long and broad, rounded at the end, and of the same reddish brown as the body. All the under parts are yellowish white, but with the breast and the sides under the wings beautifully marked with longitudinal rows of long and pointed black spots. The bill short, stout, and without any notch in the upper mandible, but the upper mandible projecting over the tip of the lower, and having its base bent with strong and stiff hairs ; the general colour black, but the basal part of the lower mandible whitish. The legs very stout, and of a brownish ochre yellow ; the irides of the eyes bright yellow. The female has less white on the wings than the male, and the black markings on the breast and sides less elegant and less conspicuous. In other respects there is but little apparent difference. This is popularly called the brown thrush, and also the thrasher, though for what reason the latter name has been given to it does not very clearly appear. The song of this thrush is pleasant, not unlike that of the song thrush of Europe ; and the bird is rather a favourite, though probably not upon that ground on which he

is most entitled to favour. In the nesting time he consumes a vast number of ground beetles and their larvæ, more especially those which are so destructive to the crops by eating the roots in the ground. In clearing away those noxious creatures he sometimes pulls up the young plants ; and therefore, as is the case with the rook when performing a similar service to our fields, he is sometimes accused of injuring the crops. The nests are formed in May, generally in the cover of a thick bush near the ground, composed first of sticks, then of dry leaves, and lastly of vegetable fibres, but without any plastering of mud. The eggs are usually five in number, of a pale bluish colour, and speckled over with small spots of a rusty brown colour. There are in general two broods in the year. These birds are of gentle disposition, and bear confinement tolerably well ; but, like the rest of the class, they are seen and heard to the greatest advantage in free nature.

SOLITARY THRUSH (*T. solitarius*). This is a secluded and comparatively a silent species, inhabiting the close vegetation of some of the swamps in the southern parts of the United States, and having little song, being upon the whole one of the most retiring birds of the whole family. It is a small bird, and has been described as the "little thrush" (*T. minor*), though the same name has been given to other species. It is only seven inches in length, and ten in the expanse of the wings. The upper parts are deep olive brown, without any markings ; the lower parts dull white ; the ear-coverts, the throat, and the upper part of the breast, are dull cream colour, the latter marked with longitudinal spots of blackish brown ; the margins of the wings paler than the rest of the upper part, and the tips of the quills dusky ; the tail forked, and it and its upper coverts fox colour ; the bill black, with the exception of the basal part of the lower mandible, which is whitish : the legs dusky ; and the irides black. The nest is usually placed in a tree or bush, against the upper side of a branch, and it is very compactly formed, but without any admixture of mud or plaster. The outside is formed of the dried roots of grass united with smaller and more flexible fibres, or with horse hairs if these are to be had in the locality ; and the inside is finished with very fine vegetable fibres. The eggs are four or five, of a pale greenish blue colour, with blotches of olive most numerous and conspicuous near the thick end.

WILSON'S THRUSH (*T. Wilsoni*). This species was, we believe, first noticed by Wilson, and by him called the tawny thrush, with a caution that it should not be confounded with the tawny thrush of Pennant's "Arctic Zoology," which Wilson says is the species which he has described as the wood thrush. These birds appear to breed in regions farther to the north than the United States, as they appear in the middle states only in the autumn, and again in the spring. The length is about ten inches, and the stretch of the wings a foot. The upper parts are tawny brown, and the under parts white, with a tinge of ash colour where they meet on the sides of the lower part of the breast and under the wings. The upper part of the breast and the throat are dull cream colour, but the chin is white ; the breast marked with pointed spots of brown ; the shafts of the tail-feathers projecting beyond the webs ; the bill black, with the exception of the base of the lower mandible, which is flesh-coloured ; the angles of the gape yellow ; the

eye large and dark, inclosed in a narrow ring of white; the legs long and slender, and of a pale brown colour.

Such are brief notices of the principal thrushes of Europe and North America. There are other species or varieties in both of these parts of the world; and there are very many in other parts, of which our limits will not allow us to take notice. Viewed as a family, they are indeed one of the most numerous in the whole class; and, though not gaudy, they are in general handsome birds, pleasant singers, and valuable as food.

THUJA (Linnæus). A genus of ornamental evergreen trees, mostly natives of America and the north-eastern parts of Asia. The flowers are monœcious, and the genus belongs to *Crucifera*. The arbor vitæ is a well-known plant, being common in every shrubbery. The hardy species are raised from seeds, and the greenhouse ones from cuttings.

THUNBERGIA (Linnæus). A genus of highly ornamental climbing shrubs, mostly natives of the East. The flowers are didynamous, and belong to *Acanthaceæ*. They are almost ever-flowering plants, produce seeds freely, and if not, are easily propagated by cuttings.

THYMELÆA. A natural order, containing eleven genera, and above one hundred species. They are shrubs or trees, very rarely herbs, with jointless branches, sometimes spiny, and the bark tenacious. The leaves are alternate, simple, entire, and without stipules. The flowers are regular, and for the most part collected into axillary or terminal spikes or bunches, though sometimes solitary. The perianth is single, tubular, coloured, with a cleft limb, and the lobes imbricate on æstivation; stamens definite and peregrynous, with two-celled anthers opening lengthwise, laterally or centrally; the germen is free, simple, one-celled and one-seeded. The wood of some of the genera is remarkably soft, and the fibres so tenacious as to be easily separable, appearing like ribbons of fine lace. The fibres of *Lagetta* and *Dirca* are capable of being made into cordage. The genera comprised in this order are the following, viz.:—*Dirca*, *Lagetta*, *Daphne*, *Gnidia*, *Lachnæa*, *Passerina*, *Stellera*, *Dais*, *Struthiola*, *Pimelea*, and *Trophis*.

THYMUS (Linnæus). A genus of undershrubs, some of which are cultivated as pot and medicinal herbs. The genus belongs to *Labiata*, and are universally distributed over the northern hemisphere. The powerful scent of thyme, and the essential oil extracted from it, renders it a useful plant, whether wild or cultivated.

THYSANOTUS (Dr. R. Brown). A genus of tuberous-rooted herbs, natives of Australia. The flowers are blue, finely fringed, and hexandrous, and belong to the order *Asphodeleæ*. The species, of which there are four already described, grow freely in a mixture of sandy loam and moor-earth, and are increased by division or by seeds.

THYSANURA (Leach; *THYSANOURÆ*, Latreille). An order of apterous hexapod insects, belonging to the class *Ametabola* of MacLeay, and distinguished by the more or less cylindric form of the body, provided with only six legs, and destitute of wings, which undergo no other change than an increase of size, and furnished on the under side of the body, at the sides or the extremity, with peculiar organs of motion, consisting, in the family *Lepismidæ*, of a double series of moveable appendages like false

legs, terminated by articulated setæ, and in the *Poduridæ* of an elongated appendage furcate at the extremity, and applied, when at rest, along the under side of the body. These insects are of small size, and very active, the appendages on the under side of the abdomen enabling them to perform long leaps. They are chiefly found in damp situations under stones, moss, &c. They have been much neglected by naturalists; but a valuable memoir is published in the first volume of the Transactions of the Entomological Society of London, upon the Irish species, by R. Templeton, accompanied with beautiful figures. Some of the species, however, appear to us to be established upon insects in the larva state.

These insects are very interesting, not only on account of their position amongst annulose animals (being regarded by Latreille and Leach as true insects, and by MacLeay as belonging to a distinct class, *Ametabola*), but also from the modifications in the structure of the mouth; some of the species possessing a development of the trophi as great as in the most perfectly mandibulated insects; whilst in others the mouth is so obscurely organised, that neither Latreille, Savigny, nor Templeton, have been able to trace its formation. In some species the eyes are merely rudimental ocelli, but in others they are perfectly reticulated. We may also specially notice the beautiful scales with which the body is covered, and the apparent want of spiracles along the sides of the body, and which Latreille, notwithstanding a very minute examination, was unable to discover. M. Guerin has, however, very recently presented to the French Académie des Sciences a memoir, in which he announces the existence of bronchiæ in one of the species of this order. They are placed under the abdominal segments, and by the side of those appendages which are compared to the false legs of the *Crustacea*. They are inclosed in little membranous bags of a similar organisation to those of the respiratory organs of a great number of the inferior *Crustacea*. This discovery of bronchiæ in these insects appears important in various respects, and more especially because it establishes a link between two classes hitherto regarded as certainly separate as regards their mode of respiration.

TICK. The species of insects of which the genus *Ixodes* is composed are thus named. They are of small size, and belong to the class *Arachnida*, and order *Monomerosomata* or *Acari*. The body is swollen and leathery, having on the upper side, in front, a scaly plate. The head is small, and furnished with a powerful rostrum composed of two retroserrated plates, which the insect inserts into the flesh of dogs and other animals upon which it is parasitic, and upon whose blood it subsists. The palpi are articulated, and enclose the sucker. In the West Indies they attack the horse and ass in such quantities, that it is the usual practice to have these animals fetched up from grass once a-week to be "ticked." They especially attach themselves at the base of the ear, and, if neglected, will sometimes become so numerous that the animal loses all power of raising its ears at will. Their powers of reproduction are so great that the animals attacked sometimes sink under their attacks.

The typical species is the *Ixodes ricinus* (*Acarus ricinus*, Linnæus), which is parasitic on the dog. It is serviceable to anoint the infested parts with oil or soft soap. The species of this genus require a more

minute examination than has hitherto been given to them. There is an interesting memoir upon their curious mode of oviposition contained in the last part of the *Annales de la Société Entomologique de France*.

TIGRIDIA (Jacquin). A genus of bulbs, natives of Mexico, bearing remarkably curious, though fugitive, flowers, belonging to the class *Monadelphica* of Linnæus, and to the natural order *Iridacææ*. The plants flower well in the open air; and, as soon as the flowering is over, the bulbs must be taken out of the ground, and hung up in a dry warm room all winter, and replanted in spring, when all danger of frost is over.

TILIA (Linnæus). A genus of deciduous timber trees, commonly called the lime or linden-tree. The flowers are polyandrous, and the genus ranges among the order to which it gives a title, viz. :—

TILLIACEÆ. A natural order, containing twelve genera and above seventy-seven species. The order consists of trees, shrubs, and many worthless herbs, none of which are remarkable for the beauty of their flowers, though some are fragrant. The lime is a forest-tree; and *Sparmannia* and *Entelea*, as greenhouse plants, are amongst the most conspicuous in the order. In general the leaves are simple, alternate, and with deciduous stipules. The inflorescence is axillary or terminal, racemose or paniculate, seldom solitary, and the flowers are regular and united. The calyx is formed of four or five sepals, free or connate, and valvate in æstivation. The petals are equal in number to the sepals, and alternate with them, combined at the base, or free. The stamens are indefinite and distinct, filaments often sterile, anthers two-celled, and opening lengthwise. The germen is formed of from two to ten carpels. The style, when present, either free or united, and with the stigmas equal in number to the carpels. The fruit is dry, or like berries, of several cells, or by abortion one-celled. The bark of most of these plants is tough and strong, easily separable into layers, and from which mats, baskets, and cords are made. Lime-trees grow to a very large size; the timber is light, soft, smooth, close-grained, and not liable to be worm-eaten, and therefore fit for carvers and toy-men. The flowers are the resort of bees, and the honey extracted is highly esteemed, and called *Kowno* honey. It is propagated by layers, cuttings, and seeds.

TILLANDSIA (Linnæus). A genus of rigid-leaved herbs, natives of the warmer parts of the tropics. The flowers are hexandrous, and the genus belongs to *Bromeliacææ*. They are easily grown in the stove, and increase themselves by suckers.

TILLIDÆ (Leach). See **CLERIDÆ**.

TILLUS (Olivier). A genus of coleopterous insects, belonging to the family *Cleridæ*, having the antennæ terminated by a serrated mass, the last joint of the labial palpi large and securiform, and the third and fourth joints of the tarsi dilated. The species are not numerous, and are found on the trunks of old trees, or in decaying stumps. There are three British species, the type being the *Chrysomela elongata* of Linnæus.

TIN. A mineral known and employed for useful purposes from the remotest ages. Tin was in common use in the time of Moses, and was obtained at a very early period from Spain and Britain by the Phœnicians. The native oxide is the principal ore of tin, and the metal is obtained by heating it to red-

ness with charcoal. It is found in abundance in Cornwall, Spain, and Saxony, as well as in the East Indies and South America. Its primitive crystal is an obtuse octohedron, of which the modifications are extremely numerous. It may be proper to add, that, in some of the valleys of Cornwall, tin is found in rounded nodules, mixed with pebbles and fragments of rock.

TINEIDÆ (Stephens; *PHALÆNA TINEA* p., Linnæus). A very numerous family of lepidopterous insects, having the wings more or less convoluted when at rest; the palpi generally four in number, the maxillary pair being often exposed and very distinct; the front of the head is clothed with long and erect scales forming a kind of crest; the antennæ often ciliated internally, and never exceeding the body in length; the usual colour of the upper wings being rather sombre, white, ochre or buff being the most prevalent colours, metallic tints being seldom found amongst them; the posterior wings are generally plain. Such are the characters by which Mr. Stephens separates a portion of the Linnæan *Tineæ* from the *Yponomeutidæ*; amongst which latter are placed the Japan moths with long horns (*Adetæ*), and many minute and splendid species ornamented with metallic markings. But the study of the minute *Lepidoptera*, as regards the relations of the different groups, may be said to be yet in its infancy. It is true that the figures of many species have been published, in which the markings of the wings are accurately displayed; but the real structure of the insect in its various details, as the position of the wing-nerves, the antennæ, parts of the mouth, legs, &c.; but, above all, the transformations of the different species, have been so much neglected, that it is impossible to construct at present any thing like a true classification of these tribes; and hence it is that we find in the works of Curtis and Stephens the greatest disagreement, not only as respects the outlines of the families, but even of the genera. In this case, therefore, it would be useless to give a list of the genera. It will be sufficient to mention that the most conspicuous genera placed in the family by Stephens, are *Galleria*, Fabricius; *Ilithyia*, Latreille; *Phycita*, Curtis; (*Phycis*, Fabricius, &c.); *Crambus*, Fabricius; *Ypsolophus*, Fabricius; *Lampronia*, Stephens; *Gracilaria*, Haworth; and *Tinea*. Some of these have been already noticed under their respective names. The typical genus *Tinea*, as restricted by Stephens and Curtis, comprises the species generally known under the name of clothes-moths, which have the head very woolly, or rather furnished with a crest of elongated erect scales; the wings incumbent in repose and glossy; the maxillary palpi are as long as the maxillæ; the larvæ of these insects are very destructive to woollen cloths, feathers, furs, &c., which they feed upon, making cases of these materials in which they reside. Amongst the species of this genus (which comprises fifteen British species), the *Tinea tapetzella*, *vestianella*, *pellionella*, and *destructor*, are the most obnoxious. The proceedings of these larvæ in the construction of their tube-like abodes have been detailed by Reaumur and others, and which are made closely to fit the body of the caterpillar, and are enlarged from time to time according to its growth. This is effected by adding to its length bits of materials upon which it feeds, so that by causing it to feed upon stuffs of different colours, its case assumes the appearance of a Scotch plaid, as well as

by also widening it by partially slitting the case on the two opposite sides, and then adroitly introducing between them two pieces of the requisite size. The following practical observations are from the valuable work of Mr. Curtis: "Wherever these insects take possession, the only chance is to discard every thing composed of wool or hair if possible; and those things that are indispensable should be constantly used, or continually brushed and exposed to the light and air. All mattresses, paillasses, and sofa-cushions should be knotted with leather, not wool; and carpets ought to be cut out where book-cases and heavy furniture stand, so that the edges may be frequently turned up to be well brushed where there is no traffic. Moreen curtains and bed-hangings are very soon attacked if the room be shut up and darkened, and may be greatly injured in a few weeks. Light, the clothes-brush, and the cane are, I believe, the easiest and best remedies against the moth. It is astonishing how soon a house may be infested, for a few old birds'-nests, and even the cocoons of moths in the garden, will enable them to feed and propagate; when a female moth finding her way into the house, a colony is soon established, that it is very difficult to extirpate. I have been compelled to forego having carpets in my chambers from the devastations these little animals made; they were revelling in multitudes under my feet in the day, and flying about my candles by night; and I lately found that myriads had established themselves under the sofa-covers, where they luxuriated on the worsted knots that held the cushions together; they even attacked the small portion of feather on my pens, and my painting-brushes were frequently eaten up by them. This, however, I soon remedied by dipping them into spirits of turpentine, which is certain death to all insects. Cushions, &c. that are infested, may be cured by moderate baking. I have observed when any clothes have been attacked, that the moths invariably prefer the black suits; and so rapid are their operations, that I have found a caterpillar half grown on removing a coat which I had worn a fortnight before."

Mr. Waterton, whose observations as a practical naturalist are allowed on all hands, strongly advocates the constant use of corrosive sublimate dissolved in alcohol, as a perfect preservative against the attacks of insects when applied to the skins of birds, quadrupeds, wood, clothes, hats, the lining of carriages, furs, and ornamental feathers.

TINGIS (Fabricius). A genus of hemipterous insects, belonging to the family *Cimicidæ*, and distinguished from the restricted genus *Cimex* by having the antennæ terminated by an enlarged joint, the third joint being longer than the rest; the legs are simple, and the wings and wing-cases of ordinary size; the latter are, however, often homogeneous, and not divided into corium and membrane, as in the majority of the Linnæan *Cimices*. The species are numerous. They reside upon plants, puncturing the leaves of the flowers, and causing them to produce a kind of gall.

TIPULIDÆ (Leach; *TIPULARIÆ*, Latreille). A very extensive family of dipterous insects, belonging to the section *Nemocera*, having the sucker or proboscis short, and terminated by two large fleshy lips or beak-shaped, but perpendicular or bent beneath the breast. It contains only a pair of lancets, being in this respect very deficient in comparison with the allied family *Culicidæ*. The palpi are either turned back, or are occasionally bent forwards; but in the

latter case these organs are short, and only one or two-jointed.

This family corresponds with the genus *Tipula* of Linnæus, and, since the time of that author, has so much increased in extent, that it has become necessary to introduce a great number of sub-divisions and genera, exhibiting great diversity of structure, although referable to a single type, which is chiefly characterised by the formation of the proboscis, which, with a very few exceptions, is an instrument incapable of inflicting that severe pain which follows the bite of the common gnat, which is the type of the adjacent family *Culicidæ*; and fitted only to suck up fluids from the surface of bodies, without the power of piercing the slenderest pellicle; a peculiarity of organisation dependent upon the slight avidity for food manifested by the *Tipulidæ* when arrived at the perfect state.

The diversity of form exhibited by so numerous a tribe of insects is especially observed to prevail in the antennæ, the disposition of the nerves of the wings, the form of the head, palpi, eyes, ocelli, and abdomen, as well as in the length of the legs. The tribes which are consequently established upon these modifications are conformed to the different modes of life of the larvæ, and the names which have been given to them, indicate these differences. There is generally a strong analogy between the characters of the perfect insect and its mode of life in the larva state. For example, the plumose antennæ are found in those *Tipulidæ*, of which the larvæ are aquatic (see *CHIRONOMUS*), whilst elongated trochanters are found in those species which, whilst larvæ, were residents in fungi.

This family is divisible into the following divisions or sub-families:—

1. *Chironomides* (*Tipules culiciformes*, Latreille). Male antennæ plumose, larvæ aquatic.
2. *Tipulides* (*Tipules terricoles*, Latreille). Antennæ not feathered; head produced into a muzzle; ocelli none; larvæ terrestrial.
3. *Mycetophilides* (*Tipules fungicoles*, Latreille). Head not produced into a muzzle; ocelli two or three; trochanters elongated; tibiæ strongly spurred; larvæ fungivorous.
4. *Cecidomyides* (*Tipules gallicoles*, Latreille). Head not produced into a muzzle; ocelli none; trochanters of ordinary length; antennæ moniliform; larvæ gallivorous.
5. *Bibionides* (*Tipules florales*, Latreille). Antennæ short, perfoliated, generally with fewer than twelve joints; legs of ordinary length; larvæ often residing in rotten dung and other vegetable debris.

The chief genera comprised in the sub-family *Tipulides* are: *Ctenophora*, *Pedicia*, *Tipula*, *Niphrotoma*, *Rhipidia*, *Lasioptera*, *Limnobia*, and *Trichocera*. The typical genus *Tipula* is distinguished by having the antennæ thirteen jointed, nearly setaceous and simple, with the joints cylindrical; the legs are long, and the muzzle is moderately long and narrow. The species of this genus are numerous, and are well known under the names of crane-flies, Harry long-legs, &c. Many of them are very common, especially in moist meadows, where they may be seen rising in swarms at every step, their legs serving them as stilts amongst the long grass. The females deposit their eggs in the earth, introducing them to a short depth by the assistance of the horny and sharpened ovipositor at the extremity of the body. The caterpillars are fleshy

footless grubs, which, as soon as born, attack the roots of grass or other plants in the situation where they are produced, and in a short time the plant droops and withers for lack of nourishment. When, as is occasionally the case, these larvæ are numerous, it may be well conceived that they are capable of doing much mischief.

Reaumur is indeed of opinion that the only food of the larvæ is the rich black mould in which they are found; but from the details given by other writers, it is evident that they feed upon the roots of plants, corns, and grass; and Kirby and Spence state that on turning up a square foot of dead turf two hundred and ten grubs were found beneath it.

There are nearly fifty British species of this genus. The most obnoxious being, *Tipula oleracea* and *T. cornicina*, the first of which may be considered as the type of the genus. It is extremely abundant.

TIT, or TIRMOUSE (*Parus*). A genus, or perhaps more correctly a little group, of conirostral birds, of the great passerine order in Cuvier's system. The characters of the genus are:—the bill slender, short, conical, straight, of great strength and power for its size, covered with a few short hairs at the base, and with the nostrils nearly hidden under the feathers; the feet very stout, with three toes to the front and one to the rear, the latter with the claw peculiarly strong and crooked, and all the toes quite free to their bases; the first quill of the wing is of mean length, or so very short as to be little else than rudimental, the second considerably shorter than the third, which is the largest in the wing. These are little birds, but they are birds of the most energetic disposition, and the most active habits; they are brisk, courageous, crafty, hardy, very pugnacious, and even ferocious; but these qualities are compensated by the smartness of their appearance, and the services they render to cultivators, more especially the cultivators of fruit trees. Notwithstanding their pugnacious dispositions, they are in so far social birds that they are generally seen in small parties. They are capable of enduring all climates, and of braving every state of the weather; and their muscular power, both in the way of action and of endurance, is greater than that of any other little birds, being well adapted to their bold and daring spirit.

We might naturally conclude that all this energy and power are not given them without an adequate purpose; and accordingly the office which they specially perform in nature, is one where the greatest energy and strength, combined with lightness of body, are required. Their chief office is to find and pick out from their hiding places in the bark, and especially the buds of trees, those insects and larvæ which no other birds can discover, or at all events capture. The lightness of their bodies, the rapidity of their motions, the astonishingly firm clutch which they can take with their feet, their keen and almost microscopic vision, and the readiness, smallness, and firmness of their bills, fit them admirably for the office. To see one of them reconnoitring a tree is quite a treat; it gets from bud to bud, one hardly knows how, for though we must suppose, from the analogy, that it can be done only on the wing, yet it is so momentary in the whole performance that the wings are not seen to move. The bird is clinging to one twig this instant, and in another instant it is clinging to another, but how the transition is made there is no time for observing; thus, the way in which

it may come to the branch is a matter of no consequence, in so far as the sure footing of the bird is concerned. Upwards, downwards, latterly, outwards, or inwards, all are the same to the tit, for it never misses its clutch, and the position in which it may hang to the twig, or whether it hangs by one foot or by both, seems to be a matter of perfect indifference. Wherever the feet touches it is sure to gain a firm hold, and the instant that the foot is detached the wings are ready to receive the bird, whether the detaching be the result of intention or of accident. Thus they are enabled to clear of their insect destroyers those tips of the slender sprays which no other birds can command, and where yet the depredations of the insect are the most destructive; as perpetrated there, they stop the leading shoots, and destroy the symmetry of the tree. The services which these birds render in this way are very great, but they are performed with so much celerity that they do not appear in their full amount to our comparatively close and dull observation. Our incapacity of fully observing and appreciating them does not, however, in the least detract from the real value of the birds.

In their resources in the way of provisions, these birds are as remarkable as in the rest of their economy; though, when these are to be had, they prefer insects and their larvæ to every other kind of food, yet when the annual supply of these is over—and it is sooner over with them, as their business is chiefly with buds, and ceases when the shoots have acquired a certain degree of length—they have recourse to the farinaceous and oily seeds of vegetables, and they do not scruple to eat carrion if it comes in their way. They also stand accused of visiting the nests of other birds in the absence of the parents, and punching open the heads of the young and eating the contents. They are said to do the same to any sickly bird that may come in their way; but perhaps their doings in this respect may be a good deal exaggerated.

In the construction of their own nests they display a great deal of labour, and often not a little of ingenuity. The different species, and especially some of the sections into which the genus has been parted, differ much in this respect. Some build about the most elaborate structures that are to be met with among birds, an instance of which will be found described at length by referring to the article BOTTLE-TIT, in the first volume of this work. Others form pendent nests at the end of the slender twigs which hang over streams and ponds; and many build in the holes of old trees; but wherever the nest is placed, it is always concealed or secured with great care, and rendered peculiarly warm and comfortable for the young; and all of them have more numerous broods than almost any other birds of the order. Thus we find that their powers of reproduction, as well as those of endurance, are suited to the very laborious office which they have to perform in the economy of nature.

Cuvier divides them into three sections or subgenera:—first, the *pari*, or tits properly so called; secondly, those which have been called bearded-tits, from the mustachios which are at the angle of the gape; and thirdly, those which have been called pendulous tits, from the fact of their suspending their nests from the ends of twigs. Some further divisions have been made by others, but they are of too minute a character for popular notice. See the

articles BEARDED-REED BIRD, BLUE-TIT, and BOTTLE-TIT.

The tits properly so called have the characters which have been mentioned as denoting the genus,

GREAT TIT (*P. major*). This is a small bird, though a great one among tits. The general colour of the upper part is olive green, and that of the under part yellowish. The top of the head is black, marked off by bands of white along the temples, and the upper neck is yellowish. It is about five inches and three quarters in length, and eight inches and a third in the expanse of the wings. It is a very common bird in most parts of the eastern continent, migrant in the extreme north, and moving from the woods to the neighbourhood of houses in winter in the middle latitudes; but in most places it is a stationary bird, or, at all events, one which does not move far in latitude, though it may occupy different kinds of surfaces at different seasons of the year. They are most active birds, clearing the trees of insects with great dexterity. They are also bee-eaters, and rather injurious in situations where hives are numerous. They eat nuts, beech-mast, and other oily fruits, and they hold a nut very neatly in their claws, while with the bill they punch a hole in the shell, and very speedily extract the kernel. The nest is constructed of moss externally, and lined with down, feathers, or other soft matters; and the birds always prefer a hole of a tree, a wall, or some other substantial cover and concealment. The eggs vary in number; sometimes they are not more than six, but they are more frequently as many as ten or twelve. The young are produced in a very immature state, and quite blind, in which condition they remain for a few days; but they grow rapidly, and in about two weeks after coming out of the shell they are able to take to the wing. The young keep in company with each other during the remainder of the year in which they are produced; and they arrive at their full size when about six months old. They have nothing that can be called a song. In the pairing time their chirp is not unpleasant; but at other seasons it is rough and grating, something like the crushing of a cinder under the foot. This bird, not having any musical powers, need not be confined in a cage as a songster, and its pugnacious disposition makes it a very unsafe companion for song birds; but, if in a cage by itself, it may be taught some amusing tricks.

COLE-TIT (*P. ater*). This is a much smaller bird than the former, being not much more than a quarter of an ounce in weight, while the great tit weighs about an ounce and a quarter. This one has the head black, the hind head white, and the rest of the upper part ash colour; the white extends some distance down the breast, and passes into yellowish white on the rest of the under part. The nest is always placed in concealment, and carefully made. A hollow of a tree, and the thickly matted herbage at the base of a young pine, or even close furze or broom, affords it not an inappropriate locality. The eggs vary from six to ten or twelve, but rarely the latter number. They are of a pure white colour, delicately spotted with rusted red. It is more of a forest bird than the great tit, and seldom comes to the vicinity of houses unless in very severe weather. Its usual food is insects and their larvæ; and in the winter season it hunts the crevices of the bark and the hybernacula of buds, for any insects, larvæ, or pupæ, that may be lurking there. Small as it is, it is very

hardy and very generally distributed, being met with in the whole range of the eastern continent, from Lapland to the Cape of Good Hope. It is not, however, so generally seen, as the great tit or the blue; but that is as much owing to the peculiarity of its haunts as to the absolute inferiority of its numbers. It is a very wary little creature, and as it runs on the bark of trees with nearly the same celerity as the creepers, and runs in any direction, the sight which can be had of it is very momentary. With the exception of the long-tailed one (see BOTTLE-TIT), it is the smallest of all the British species.

THE MARSH TIT (*P. palustris*) is also a small species, though nearly one half heavier than the cole-tit. Its colours are similar; that is to say, the head is black, and the general tint of the rest of the upper plumage greyish. The back wants the greenish tinge which it has in the preceding species, and the head is not so black. The whole plumage is also less glossy. Though called the marsh tit, this cannot be considered as a marsh bird in the proper sense of the word, as it is not found in the fens, or actually feeding or living over the water in any situation. But it is fond of humid places which have a tangled vegetation of brakes and osier beds, and the stumps of old willows, alders, and other trees that like marshy places, but not absolutely the marshes themselves. It is a hiding bird, and not very often seen in proportion to its actual numbers. The nest is usually in the hollow of the stump of an old tree; and on this account osier plantations and oak copses which are cut for bark, and both of which are usually near the banks of streams, are favourable nesting places for this tit; but if these are not to be had, it seeks the cover of a brake or bush, or the thick underwood at the root of a tree. The nest is formed of moss, lined with softer matters, such as the down of the willow. The eggs are about the same in number as those of the cole-tit, and not very different from them in appearance, only they are a little larger in size, and rather more speckled about the thick ends. In summer the marsh tits consume great numbers of flies, bees, wasps, moths, and all the winged insects which are found in their localities. In winter that supply fails, and they are obliged to shift their ground. They do not frequent the trunks and branches of high trees so much as the other tits; but rather eat the ends of the larger *Compositæ*, many of which are sweet, and contain a great quantity of nutritious matter in a very small compass. In extreme cases they approach houses and farmyards, and readily eat any garbage that comes in their way. They are not so gay in their plumage, nor so active in their conduct, as the great tits, and especially not as the blue ones, but still they are lively birds.

THE CRESTED TIT (*P. cristatus*) is a woodland species, most abundant in the cold latitudes and in upland places; it prefers the pine forests, and especially the junipers, and other close evergreens of more lowly growth, to the tall pines and spruces. It is exceedingly rare as a British bird, if it be any thing more than an accidental straggler. The upper parts are reddish-brown ash; the cheeks and sides of the neck are whitish; and the feathers on the top of the head stand up and form a sort of crest of a pyramidal shape, of which the individual feathers are black with white borders, which gives it altogether a hoary appearance. There is also a streak of black along the temple, and a black collar on the neck. The under

parts are reddish white, and the bill and feet lead colour. The length of this bird is about four inches and a half. It rarely quits its habitation among the close evergreens, even in the severest weather; for such places afford shelter at all times, and very generally food. The nests are in holes of trees, or other concealments, and not unfrequently in the deserted nests of other birds which build earlier in the season; but those they line and trim up, so as to give them that compactness and warmth which are characteristic of the nests of this family. Their eggs are ten or twelve in number, of a white colour, with small spots of dull red.

There are very many other species in all the three great divisions of the eastern continent, in Australia, in New Zealand, and in America; but they are not found in the very warmest and richer parts, as in central America and the Oriental Isles.

The "bearded reed-bird," already referred to, will serve as a specimen of Cuvier's *Moustache*, and indeed it is the only one that can be given, being the unique species of the division as far as is hitherto known. It reflects much credit upon the acumen of the great naturalist of France, that he should have separated this bird from the tits upon the ground of its organisation alone, and that this should be completely borne out by the habits of the bird, now that these have been ascertained with tolerable accuracy. His division *Ramiz* contains two species of which the nests are peculiar; one of them, a native of the south of Europe, and the other of the south of Africa; and it might not perhaps be amiss to give them the old specific name of the first of these, *Pendulinus*, as a generic one.

Pendulinus Narbonensis. This bird, to which some have given the very inappropriate name of the "mountain titmouse," is a marsh bird, frequenting the marshy banks of streams and pools, generally in lonely and desolate places where its haunts are not liable to be visited. It skulks about in a very wary manner, and is not often seen, and very seldom caught. It is met with in the south of France, in Italy, in the valley of the Danube, in the marshy parts of the south of Russia, and in Siberia. The upper parts are reddish grey; the nape and top of the head ash; the forehead and head as far as the eyes, and also the ear-coverts, black; the rump ash colour; the quills and tail-feathers blackish, margined with whitish red, and tipped with white; the throat white; and the rest of the under part white, with a rosy tinge. The bill is black, straight, rather long, and very finely pointed; for which we shall see that the bird has use, besides the capture of its food.

We mentioned that these birds inhabit marshy places, and they always have their nest at the end of a flexible twig pendulous over the water, by which means it is perfectly secure from reptiles. The chief material which they use is vegetable down, obtained from the willow, the poplar, from dandelion, thistles, and a variety of other plants which grow near the streams; this they weave into a frame or basket work of long, tough, and slender fibres, till it has the appearance and consistency of a piece of felt. It is closed above and firmly fastened to the twig by strong but flexible fibres, and they line the inside with a coating of the finest and softest down, so that the nest is as warm and comfortable as if it were lined with fur. The shape varies in different nests, and of course sometimes one kind of down predominates,

and sometimes another; but the fabric is always the same. The lateral opening by which the birds enter is toward the water; and it often has a ledge or rim upon which they can alight, and feed the young after they break the shell, without actually entering the nest. The eggs are usually about six in number, of a white colour, with obscure spots of red. The birds are as attentive to the feeding of their young as they are to the construction of their pendent cradles; and there are indeed very few birds which have more labour in preparing for and rearing their progeny, and none that perform the work in a more elegant manner. We admire the nest of the heath-tit, and it is really a very pretty structure; but it is a fixed nest, and that of these birds is wholly at the mercy of the winds, and the flexible twig to which it is suspended contributes not a little to the safety of the fabric, and the comfort of the young birds while they are in it. The birds themselves are, as we have said, but seldom seen; but the nests are met with in considerable numbers, and command the admiration of the rustics. It is probable that the nests last for several years, with very little repair; and instances have been found of other birds hatching in them at a very late period of the year. The people of some of the wild parts, who are not a little prone to superstition, have a very strong impression of the protective virtues of these nests, for they hang them up over the doors of the cottages, quite sure in their own minds that, while the nest is there, the dwelling and its inmates are quite safe from the stroke of the lightning. Some have given it as their opinion that the first nest which a pair of these birds build is but a flimsy fabric, though even then it stands the weather; but that in succeeding years they give it an additional layer of materials on the outside, firmly incorporated with the former. This, however, wants confirmation.

P. Capensis. This, as the name indicates, is a native of Southern Africa. It is about five inches in length. The upper part greyish ash; the quills black with whitish margins; and the tail black on the upper surface, and white on the under. The under parts are bright ash colour, and the bill and feet black. Although the country which this bird inhabits differs a good deal from that inhabited by the preceding species, the mode of constructing the nest is very nearly the same; and indeed it is, in some respects, a more curious nest than the other. The principal material used for the fabric is the down of plants, as well as in the other; and the down of some of the *Stapelidæ*, which are so abundant in Southern Africa, is that which presents itself most readily. The principal nest is for the female and the eggs, but there is a separate and smaller apartment, which is entered by a tubular porch; and this serves as a lodging for the male, while the female is occupied in the duty of nidification. Both birds assist in constructing the nest, and both share in the protection it affords.

TODY (*Todus*). A genus, or rather small group, of syndactylic birds, which have sometimes been confounded with the fly-catchers and fly-hunters, from both of which, however, they are quite distinct. The birds which they most nearly resemble are the kingfishers; and, though the habits are not the same, they may be said to hold among American birds (to the tropical parts of which continent they are confined), the same place that the kingfishers hold in the ornithology of the eastern continent.

They have the bill large, depressed, obtuse at the

tip; the tarsi rather long; three toes to the front and one to the rear, the inner front toe united to the middle one as far as the second articulation, and the external as far as the third; the wings short and rounded. They nestle on the ground near the water, and have the nest under a projecting bank, so formed that it is protected from the rain. It is composed of a few straws and stalks, lined with downy matters. The eggs are four or five in number, of a grey colour, spotted with brown. The female bird sits with great constancy, and the male is assiduous in supplying her wants, and in feeding the young when they appear. In the pairing time the male has an agreeable little song, and the female often repeats a sort of call-note; but at other times they are remarkable for their taciturnity. They are very pretty little birds, feeding upon insects, and perfectly inoffensive in their manners. Though their wings are short, their flight is rapid and straight forward. They are perched sometimes in trees and bushes, and sometimes on stones and elevated points of the earth; but their colour is so like that of the bright green trees, that they are seen only in the latter situations. There is only one determined species—

GREEN TODY (*T. viridis*). The upper parts are altogether of a most brilliant green colour; the forehead is yellowish-green; the quills and tail-feathers brown, with green borders; the throat and fore-neck are of a bright red, with a gloss of bright orange, and the extremity of each feather fringed with white; there are white feathers at the angles of the gape, which extend toward the ear-coverts, where they rise into a tuft of pure aquamarine blue. The under part of the body is whitish, passing into bright rose-colour on the flanks; and the under coverts of the tail are greenish-yellow; the bill is yellowish-grey, with the tip black; and the feet are reddish. The total length of the bird is three inches and a half.

TOFIELDIA (Hudson). A genus of herbaceous perennials, natives of the northern parts of Europe and America. The flowers are hexandrous, and the plants are ranked among the *Melanthaceæ*. The species should be planted in moist peat-earth, and are increased by division.

TOMICUS (Latreille). A genus of coleopterous insects, belonging to the section *Tetramera*, subsection *Xylophaga*, and family *Scolytidæ*, comprising the destructive little insects known under the name of *Typographer*, or printer beetles. See the article **BOSTRICHIDÆ**.

TOPAZ. A mineral which derives its name from Topazos, a small island in the Red Sea. It is principally found of a wine-yellow colour, but is in some instances of a violet-blue. A single specimen of the latter colour, which is very rare, was sold for 1500 ducats at Vienna. The topaz occurs in Europe, Asia, and America. Those found in Brazil, which are so much esteemed in commerce, are dug in the district of Villa-Rica.

TORMENTILLA (Linnæus). A British genus of creeping perennial herbs, commonly called sept-foil, belonging to *Rosaceæ*. This genus was formerly in repute for allaying the pain of toothache, but is now neglected.

TORTOISE. See **CHELONIA**.

TORTRICIDÆ (Stephens; *PHALÆNA* **TORTRIX**, Linnæus). A family of small lepidopterous insects, belonging to the section *Nocturna*, or moths, distinguished by the peculiar position and outline of the

wings when at rest, the anterior pair being broad, and, when closed, forming a triangle dilated on each side anteriorly, and very slightly deflexed, thus somewhat resembling a bell. The palpi are generally only two in number; the head seldom deeply crested; the antennæ short and simple.

The family is exceedingly numerous, not only in species, but also in individuals, many of which "reside in the larva state within a leaf twisted or convoluted, by the larva itself, though some few reside within the pulpy substance of fruits, or even the medulla of plants. The caterpillar is usually naked, slender, with sixteen legs, and is very active, running with great rapidity either backwards or forwards." (Stephens' Brit. Ent. Trans. iv., p. 63). These little moths are seldom ornamented with metallic or brilliant colours, but they are, nevertheless, prettily varied with tints of grey, brown, buff, &c. Many of the species seem to be more especially attached to forest trees, the oak, birch, elm, &c., being occasionally very much infested with them. This is particularly the case with the oak, which in some summers is completely denuded of its leaves, over a great extent of ground, by the *Tortrix viridana*, a pretty little species, generally about three-fourths of an inch in expanse, having the anterior wings of a fine pale green colour, the anterior margin being whitish, and the posterior wings brownish. The female lays her eggs upon the leaves of the oak, which the caterpillar ingeniously curls up, fastening the curls of the leaf with silken threads, and thus constructing not only an abode in which it resides, and which fits the size of its body, but also securing a magazine of food, in the midst of which it takes its station, and in which, after having attained its full size, it becomes a pupa. When ready to escape, it protrudes the head part of the chrysalis out of one end of the whorl of the leaf, and then makes its escape. So numerous is it at certain times, that, by beating an oak brush, whole showers of the moths are shook into the air.*

Two other species, being the largest of the family, also feed upon the oak. These are the *Tortrix prasinana* of Linnæus, and the *T. quercana*, constituting the genus *Hyalophila*, Hubner (*Halias Treitschke*, Curtis); the latter of which varies in the expanse of the wings from an inch and two thirds to two inches. These are also of a green colour, with narrow oblique white bars on the upper wings. The caterpillars are not inclosed in a roll of leaves, and are naked, sub-cylindrical, and fleshy. They construct a very curious boat-shaped cocoon on the undersides of the oak leaves.

The species of the genus *Carpocapsa* comprises various species, which, in the larva state, feed upon the fleshy pulp of different fruits, *Carpocapsa pomonella* being the insect of which the grub is so often found in the inside of apples and pears, of which it causes the destruction, by depriving the stalk of its support. Several species of the genus *Orthotomia* (*Tortrix turionella*, Linnæus, *T. resmella*, Linnæus) reside in the larva state in the interior of the cones of firs of various kinds, which they greatly injure.

The family comprises more than three hundred British species, divided into a great number of genera, established upon minute structural differences, which it would require far too great space to detail, or even to give the list of the genera, which are by no means fully established at present, the observations made under the article **TINEIDÆ** being equally applicable to the **TORTRICIDÆ**.

TOUCAN (*Ramphastros*). A genus of zygodactylic or climbing birds, having the following characters: the bill cellular, very large, and much longer than the head, broader than the forehead, and higher than the profile of the head, nearly straight in the greater part of its length, but a little curved toward the tip of the upper mandible, with a very conspicuous ridge on the culmen, and the tomia, or cutting edges of the mandibles, in general toothed. In the living bird the bill is generally beautifully coloured with brilliant prismatic reflections; but the colours fade, and the reflections go off entirely after the bird is dead. The nostrils near the base of the bill, partly covered by a horny lamina of it, and surrounded by membrane; the feet stout, with four toes, two to the front and two to the rear, the front ones united as far as the first articulation, and the external one longer than the tarsus; the wings of mean length, concave, and rounded, the third and fourth quills being the longest; the tail feathers ten in number.

The bill of the toucan seems so very large that the bird must be burdened by the weight of it; but it is in general very thin, and the parts of it which are thickened for giving it strength are not solid bone, but two very thin laminæ, very finely united by cross partitions, which give the maximum of strength with the minimum of substance, and the cellular openings which they form are filled with air, in the same manner as the cells of the hollow bones of birds; the food is seized with the sides of the bill, and before it can be swallowed the bill must be vented, and the food is kept in its place against the hollow of the upper mandible, by means of the feathered or barbed tongue. The action of the wind upon the bill appears to be that which is the most inconvenient to the birds, as they never fly or perch but with the bill to the wind. They eat fruits and insects, and in the summer they are great destroyers of the eggs of other birds. They nestle in the holes of trees, and keep very closely to the woods in the richest and warmest parts of the American continent, the only part of the world in which they are to be found. There are two sections or sub-genera of them, *Aracaris*, and *Toucans*, properly so called, which do not appear to differ very much in their manners. Some account of the whole, and of the place which they occupy in nature, will be found on reference to the article *ARACARI*, so that here we shall only have very briefly to notice the leading members of the toucans, properly so called.

The two sections inhabit the same regions, or, at all events, regions which are very similar. The toucans have the bills considerably broader than the head; the aracaris not quite so broad, and the horny covering of the bill is less compact and strong in the toucans than the others. Toucans are, in so far, social birds, for they are in general seen in small troops of about ten or a dozen; they are usually seen upon the wing or on trees, and rarely upon the ground, where their action is rather awkward. They do not walk but leap, and their hopping is ungainly, as their feet are very wide apart; this, however, gives them some advantage when they perch. On the wing their flight is straight forward, and the great bill is elevated so that it is rather above the axis of the body. Though zygodactylic they do not climb, either upon the boles of the trees like the woodpeckers, or upon the twigs like the parrots; they leap from one branch to another, using the wings for support, whether the leap be for a shorter distance or a longer. This dif-

ference of action upon the trees shows at once the difference of habit between the toucans and the other tree birds which we have mentioned. The food of the woodpeckers and other bark birds consists of substances which they obtain from the crevices of the bark, in small portions at a time, and that of the parrots of fruits which the birds must range for among the twigs. The characteristic food of the toucans being the eggs and young of birds which build in trees, is found in much larger quantities, and therefore it is sought for by more extended and energetic action than that of the others.

Like the nest-plundering birds of our own country, the toucans have no song, but only a harsh grating cry, bearing some resemblance to that of the raven; they are also very easily tamed if taken young, and far from particular in their food, though they require a good deal of it.

After the aracaris are separated, there is a pretty strong family likeness among all the true toucans, and the specific differences are in reality little more than differences of marking; for in them all the general colour is black, and the other colours, which are often very rich, are on the throat, breast, and rump. The following are the leading species.

WHITE-THROATED TOUCAN (*T. erythrorhynchus*). The upper parts black, the upper tail-coverts greenish yellow, the foreneck and upper part of the breast pure white, the rest of the under parts dead black; the upper mandible of the bill black, with a band of grey surrounding the base; the lower mandible red, with a band of blackish grey, and the feet greenish. This species is abundant in Guiana. The length is seventeen inches; it is, however, to be borne in mind that the tails of the toucans are long, and that the bodies are not quite so heavy as the length compared with that of the majority of other birds would indicate.

YELLOW-THROATED TOUCAN (*R. discolor*). The upper parts black with green reflections; the cheeks and throat greenish yellow; the breast, the upper part of the belly, and the coverts of the tail, bright red; the bill black at the base, grey in the distal parts, and red on the margins, and the feet blackish. This species is about the same length as the preceding, and found abundantly in some parts of Brazil.

TACO TOUCAN (*R. Taco*). Upper parts dead black, with the exception of the wings and tail, which have some lustre in the colour; the upper part of the neck white; a large gorget on the breast, and the under coverts of the tail, crimson; the bill curved in the form of a scythe-blade; the upper mandible yellow and greenish brown, these shades of colour separated diagonally by a black line; the lower mandible entirely of a greenish brown; the feet olive ash; the length twenty inches. This species has been met with in Paraguay.

TINAI TOUCAN (*R. tucanus*). Black on the upper part, with bronze reflections; cheeks, throat, and foreneck orange yellow; coverts of the tail sulphur yellow; the bill very long; the upper mandible green, with three large triangular spots of orange-yellow on the sides, a yellow streak on the culmen, and the tip blue; the lower mandible blue, clouded with green about the middle of its length; the feet bluish ash. The length twenty inches, and the native country Brazil.

There have been various other species mentioned, but they have little difference except in colour; so that when one is mentioned all the rest may be

readily understood, in so far as they have any popular interest.

TOURACO (PLANTAIN-EATER, *Musophaga*). A limited group of African birds, of which the place is not very clearly defined. They agree in the form of the wings and tail with some of the gallinaceous birds of the forests of central America; and they have, like them, three toes to the front, with a short membrane between the bases, but the outer toe is in general reversible, so as to make a perching though not a climbing foot, as it is in many of the owls. They are inhabitants of the close and rich woods by the banks of the rivers, and subsist chiefly upon different species of plantains and other succulent fruits. They nestle in holes of trees, and rarely quit the thick woods, or even alight on the ground within them. They can find appropriate nesting places with very little labour in the kinds of forests which they frequent; as there are always many of the trees in a state of natural decay, or internally reduced to powder by the labours of those insects popularly known by the general name of white ants. In their nests in the holes of the decayed trees, the female deposits four white eggs of rather a round shape, upon which she, alternately with the male, performs the incubation with great assiduity. The young birds remain in the company of their parents until the season of incubation again comes round. We shall shortly notice the two genera or sub-genera, the one of which has received the name *Corythair*, as including the *Touracos* properly so called; and the other that of *Musophaga*, or the plantain-eaters.

CORYTHAIR. These have the front plumed to the base of the bill, and a moveable crest on the top of the head.

Buffon's Touraco (*C. Buffoni*). General colour of the upper part bright green, with the quills and tail-feathers violet-blue; the head with an erectable crest situated on the nape; the lesser coverts of the wings green, the middle ones greenish-blue, and the larger clouded with the same violet-blue as the quills and the rump; a black spot under each eye; the under parts green, but a little paler in the shade than the upper parts; the bill carmine-red; and the feet black. The length of the mature bird is about seventeen inches. This species occurs in many of the more richly-wooded parts of the American continent; it is a very beautiful bird, and, as far as is known, very gentle in its manners.

Green and White-crested Touraco (*C. Persa*). This species has been, oddly enough, called a cuckoo by some of the authorities. The upper parts of it very deep and brilliant green with purple reflections; two white streaks across the region of the eyes, with a streak of purple between them; the naked membrane surrounding the eyes red; the head ornamented with a crest of numerous long and thread-shaped feathers, which are distributed in two rows that meet along the mesial line of the head; these feathers are the same green as the rest of the upper part for the principal part of their length, and white at the tips; the rump is blackish-green; the upper coverts of the tail very deep green; the primary quills are bright chestnut-red; the mandarin red, margined with brown; the tail-feathers deep green on the upper side, and blackish on the under, with the tips black; the lower parts green; the feathers on the thighs streaked with black; the bill whitish; the feet blackish; the length eighteen inches; and the habitat the rich woods of tropical Africa.

Red-crested Touraco (*C. erythrolapha*). Upper parts copper-green, with very bright metallic lustre; the crest on the head forms a sort of helmet, consisting of two close rows of very fine feathers about two or three inches long, which meet together at the top, and there form a red crest, which gradually passes into the deep green, which is the general colour of the upper part of the head; the primary and secondary quills are of a beautiful red, pale on the inner webs; the tertiaries and the coverts of the wings are green, with reflections of blue; the tail-feathers and their coverts are deep and rich bronze-green on the upper side, and a line of green on the under; on each side of the head there is a large patch of white which extends up to the forehead, near which it acquires a reddish tinge; the borders of the eyes are purple-red, with a tinge of blue; the bill is yellow; the feet are ash colour; the length is about seventeen inches; and the habitat Southern Africa.

These are the leading crested species, with the forehead feathered down to the base of the bill; and from the short notice which we have given, it will be readily understood that they are very rich ornaments in the luxuriant forests of which they are natives, from their beauty, their size, and their gentle and inoffensive manners.

MUSOPHAGA. These are understood to feed more exclusively on the banana and other sweet and succulent fruits, than the members of the preceding division. Like them, their place in the system has been misunderstood by some. They may be considered as the birds which, in their general characters, approach nearest to the *Alectoridæ* among the gallinaceous birds. See *ALECTOR* and *GALLINIDÆ*. They have the upper mandible advanced on the head in a horny plate, which partially recurves over the front.

Gigantic Plantain-eater (*M. gigantea*). The upper parts bright shining blue; the head advanced with a black crest showing brilliant reflections of blue; the quills blue with black tips; the tail-feathers black, with a transverse band of russet; a gorget of bright green upon the throat; the under parts bright brown with clouds and glosses of red; the bill yellow-orange; and the feet black; the length five-and-twenty inches; so that in its own section, and generally among birds of such brilliant plumage, this splendid species merits the name of *gigantea*. It is a native of the equatorial parts, and the south of Africa.

Varied Plantain-eater (*M. variegata*). The upper parts greyish-ash, with an elongated spot of a blackish colour along the centre of each feather; a crest of elongated thread-shaped feathers on the top of the head, which, with the cheeks, throat, and upper part of the neck, are maroon-brown; the quills are black, variegated with white; the tail-feathers slate-grey with black tips; the under parts are white with a narrow blackish stripe along the middle of each feather; the bill and feet black; the length eighteen inches; and the native habitat the tropical part of Western Africa.

Violet Plantain-eater (*M. violacea*). Upper parts purple, with violet reflections; a large streak of white behind the eye; the quills crimson-red; the tail-feathers unequal in length, the central ones being the longest; the under part purple, marked with cloudings of ash-colour; the bill yellow, with the base of the mandibles covered by a naked skin, studded with red tubercles and extending to the eyes; the feet of a

brown colour; the length a foot and a half; and the native habitat Southern Africa. This is the species which approaches most nearly in its characters to the *Gallinide*.

TOURMALIN. A mineral that has the singular property of displaying distinct electrical phenomena by a mere change of temperature. This mineral was known to the ancients, who called it *Lyncurium*. Both *Tourmalin* and *Schorl*, with which it is associated, occur in prismatic crystals of a dark colour. This mineral generally occurs resting in beds, or single strata, and is found in every quarter of the globe.

TOURNEFORTIA (Linnæus). A genus of evergreen shrubs, natives of the East and West Indies. The flowers are pentandrous, and belong to *Boraginæ*. In the greenhouse they ripen seeds, by which they are increased.

TRADESCANTIA (Linnæus). A rather numerous genus of herbaceous perennials, many of which are ornamental. In English lists they are called spiderwort, from the irregular shape of the flowers and their appendages. They belong to *Hexandria*, and to the natural order *Commeliaceæ*. Open borders; division.

TRAGIUM (Springell). A genus of annuals, biennials, and perennials, all herbaceous. They stand in the fifth class of Linnæus, and in the natural order *Umbelliferae*. *T. anisum* is the valued anise, so much cultivated in warm countries as a condiment, and for its medicinal qualities.

TRAGOPOGON (Linnæus). A genus of herbaceous biennials, chiefly natives of Europe, and commonly called goatsbeard. They bear large composite flowers, and their seeds have feathery appendages; hence their name. The *T. porrifolius* is cultivated for its spindle-shaped root as a culinary vegetable, under the name of *salsify*.

TRAPA (Linnæus). Is a genus called in English water-caltrops; found in India and in various parts of Europe. The flowers are tetrandrous, and the genus belongs to *Hydrocharidææ*. *T. natans* is a European plant. Some of the canals at Versailles are covered with it, and the fruit is collected and eaten as chestnuts. They are called *jesuits'-nuts* at Venice; and in some places they are called *galarin*, and much eaten by the inhabitants. *T. bicornis* are common in China, and form a common ingredient in stews, &c. *T. bispinosa* are esteemed by the Hindoos.

TRECHUS (Clairville). A genus of small coleopterous insects, belonging to the family *Carabidææ*, and sub-family *Harpalidææ*, from which it is distinguished by having the terminal joint of the palpi acute and conical, but longer than the preceding joint; the body is oval and sub-convex, and the posterior angles of the thorax are rounded. They are generally found at the roots of grass by the sides of ponds or dam-banks. There are about a dozen British species.

TREMANDREÆ. A natural order of plants containing only the genus *Tetrathica*, of which there are seven species. They are all small bushes bearing octandrous flowers, with foliage particularly neat and resembling some of the heaths. They are greenhouse plants, and are easily propagated by cuttings.

TREVIRANA (Willdenow). A single but highly ornamental plant, a native of Jamaica. The scarlet flowers are didynamous, and belong to *Scrophularinææ*. This plant was called *Achimedes coccinea* by Persoon,

and *Cyrtilla pulchella* by others; it affects sandy loam and heath-mould mixed, in which it grows freely. When the flowering is over, the pots should be kept dry; and against the growing season, according to Sweet, the root should be divided and repotted, to ensure a fine bloom.

TRICHILIA (Linnæus). A genus of West India trees, having decandrous flowers, and belonging to the natural order *Meliaceæ*. In our collections they are treated like other stove plants, and are increased by cuttings of the half-ripened wood.

TRICHIOSOMA (Leach). A genus, or rather sub-genus of *Tenthredinidous* insects, separated by Dr. Leach from the genus *Cimbex* (which see), but not adopted by continental authors. The species are distinguished by their hairy bodies, and by the four hind femora being toothed. There are nine British species. Type *Tenthredo lucorum*, Linnæus.

TRICHIIUS (Fabricius). A genus of handsome coleopterous insects, belonging to the family *Cetoniidææ*, and separated from the great Linnæan genus *Scarabæus*. See *CETONIIDÆæ*.

TRICHODIUM (Michaux). A genus of European and American triandrous flowering plants, belonging to *Graminææ*. Two of them are found in Britain, viz., *T. caninum* and *T. ceteceum*; and the *T. decumbens* is cultivated in America.

TRICHOPTERA (Kirby). An order of insects established for the reception of the Linnæan genus *Phryganea*, and characterised by Mr. Kirby as follows: "Metamorphosis incomplete, mouth emandibulate, prothorax replaced by a collar; wings four, upper pair mostly hairy, lower ample, folded; neuuration branching; anus without setæ; eggs extruded in a gelatinous mass." (Introd. to Ent. iv., p. 380). Mr. MacLeay, in the *Horæ Entomologicæ*, united the *Tenthredinidææ* with this order. By the French authors the *Phryganeæ* are placed at the end of the *Neuroptera* as part of that order.

We have already given, in the article *PHRYGANEÆ*, various details relative to the structure, habits, and classification of these insects, which renders it unnecessary to enter more fully into these matters in this place.

TRIDENTEÆ (Haworth). A genus of undershrubs, natives of the Cape of Good Hope, separated from *Stapilia* by the late Mr. Haworth. The flowers belong to *Pentandria*, and to the natural order *Asclepiadææ*. Like other succulent plants, they require but little water, and should be planted in light porous soil.

TRIENTALIS (Linnæus). A genus of two little herbs, one of which is a native of Britain, and called winter-green. The flowers are heptandrous, and the plants belong to *Primulacææ*. In the flower garden they are planted in loose soil, and increased by seeds.

TRIFOLIUM (Tournefort). A very extensive genus of herbaceous annuals, biennials, and perennials, commonly called trefoil, or clover. The flowers are diadelphous, and belong to *Leguminosææ*. They are mostly European, and all more or less pasture plants; a few of them are particularly valuable to the farmer, their introduction into agriculture having advanced the profits of that business, perhaps more than any other cultivated plant.

TRIGLOCHIN (Linnæus). A genus of rushes found in bogs in various parts of the world, and belonging to the order *Juncaginææ*. All are curious, and some of them economical, for mat-making, &c.

TRIGONELLA (Linnæus). A genus of herbs,

chiefly annuals. It is allied to the clovers, and consequently belongs to the natural order *Leguminosæ*. A few of the species are British, and the rest are distributed over Europe and north-western Asia.

TRILLIUM (Linnaeus). A very curious genus of North American tuberous-rooted herbs, bearing showy hexandrous flowers, and belonging to *Melanthaceæ* (Hort. Brit.), or *Smilacææ*, according to Sweet. They require to be planted in a shady peat-earth border; they increase but slowly by division.

TRILOBITES. A very extraordinary tribe of extinct animals, known in this country under the name of Dudley fossils, having the body composed of three transverse parts, and divided longitudinally by two deep impressions, forming three elevated lobes. The anterior part of the body is generally more or less semicircular or lunate, having on the upper side two large and generally reticulated eyes, shaped like kidneys. This part is succeeded by numerous (from six to twenty-four) transverse segments, and the body is terminated by a large semicircular plate less distinctly articulated than the preceding part. Some account of these remnants of animals are given in the article

Fossil Remains. No organs of locomotion or antennæ have been observed, and it appears to have been the habit of these animals to roll themselves up into a ball by bending the extremity of the body beneath the breast, and bringing it into contact with the head. Much diversity of opinion has been entertained amongst naturalists as to the relations in nature of these curious creatures. According to M. Alexandre Brongniart, who published a good monograph of them, they are most analogous to the *Limuli* and other entomostracous crustacea, provided with a great number of legs, of a more or less membranous construction, and which, it may be readily conceived, would have been entirely destroyed during the great overthrow which has reduced these creatures to their present state. This opinion has been strenuously maintained by Audouin. It is, however, opposed by Latreille, who observes that, supposing these animals to have been destitute of legs, they would naturally approach the *Oscabriens* (or *Gasteropodous Chitons*); or rather, that they constituted the primitive type of annulose animals, uniting on one side the last mentioned molluscous creatures with the entomostracous crustacea, as well as with the genus *Glomeris* (amongst the myriapodous insects); adding, that no branchiopodous *Entomostraca* has hitherto been discovered capable of contracting itself into a ball, which peculiarity is only observed in the crustaceous genera *Typhis*, *Sphæroma*, *Tylos*, and *Armadillo* (see a figure of the last-named genus in the article **CHILGNATHA**), and in the apterous genus *Glomeris* (also figured in the last named article); between which tribes there is a considerable hiatus. The genera *Calymene* and *Asaphus*, amongst the *Trilobites*, on account of their contractility, evidently approach the *Glomeris* and some of the isopodous crustacea (*Sphæroma*); but the *Trilobites* have the terminal segment of the body entire, and not furnished with lateral swimmerets as in the *Sphæromæ*; but the same negative character exists in the *Glomeris*, and especially in the genus *Tylos*, of which the upper side of the thoracic segments is divided into three lobes. The discovery of the genus *Serolis* on the coasts of Patagonia, has afforded another proof of the correctness of Latreille's idea of the oscillant situation of these creatures between the

Isopoda and the myriapodous insects, the eyes in that genus being situated in the same vertical situation, and of the same lunate form, as in the *Trilobites*.

a *Asaphus expansus*.

b The same rolled up.

Moreover, the body is longitudinally divided into three lobes like the *Trilobites*. The legs and caudal swimmerets scarcely extend beyond the sides of the body; but the antennæ are very large and distinct. This genus has lately been described and figured in detail in the Transactions of the Albany Institute, by Mr. James Eights, under the name of *Brongniartia*. Much of this diversity of opinion has resulted from the very much worn state of the *Trilobites*, which have, in many instances, been so rubbed, that their eyes have been entirely effaced; but it is questionable whether any *Trilobite* was ever destitute of those organs which Dr. Buckland has, in his Bridgewater Treatise, described at great detail in connexion with their fitness for the situations in which the animals are supposed to have resided. Mr. J. V. Thompson, in the last of his Zoological Researches, has adopted the opinion of M. Audouin, considering that the eyed *Trilobites*, *Calymena*, and *Asaphus*, are most approximate to those phyllopodous crustacea of which *Apus* is the type, and that the genera *Bucephalithus*, *Oygia*, and *Paradoxides*, are analogous to such phyllopodous genera as *Branchypus*, *Eulimena*, and *Cheirocephalus*.

The works of Brongniart above referred to, and that of J. W. Dalmad (Ueber die Palæaden oder die sogenannten Trilobiten. Nurnberg, 1828), and the works therein referred to, must be consulted for the determination of the generic and specific characters of these perplexing and singular animals.

TRIMERA (Latreille). A primary section of the coleopterous insects, having apparently only three joints in all the tarsi; but in effect having four, the third being very minute and buried between the lobes of the second joint. Latreille introduces into this section the families: 1. *Fungicoles* (typical genera *Eumorphus* and *Endochymus*, Fabricius); 2. *Aphidiphages* (*Coccinella*); and 3. *Pselaphiens* (*Pselaphus*). The relations of these three groups seem in nowise to warrant this association; the *Fungicoles* appear most nearly allied to some of the fungivorous *Necrophaga*, notwithstanding the diversity in the number of the joints of the tarsi, and the *Pselaphidæ* are even more closely allied to the *Staphylinidæ*. The *Coccinellidæ*, on account of their peculiar characters, and the insectivorous habits of the larvæ, are a very distinct group; but, perhaps ought not to be raised beyond the rank of a family, instead of constituting a section by themselves.

TRINGA. A genus of stilt or running birds, frequenting the margins of the waters, but rarely, if ever, wading; and seeking their food on the oozy banks rather than the sandy and pebbly shores.

They have sometimes been confounded with the sandpipers, and they are certainly near neighbours to these birds, but still there is a line of distinction between them.

The tringas are more aquatic than the sandpipers; that is, they seek their food on more soft and humid surfaces, although they neither wade nor swim. Their bills are about the same length as the head, slender, straight, or but very slightly curved, flexible in its whole length, while that of the sandpipers is flexible in the basal half only. The tip enlarged and smooth, channelled to the tip, and the nostrils pierced in the channels. In its character, and it is the organ from which we can best judge of the habits of the birds, it is intermediate between the bill of the sandpipers and that of the snipes—more sentient than the former, and less so than the latter. Their tarsi are of moderate length; and the feet have four toes, three to the front and one to the rear. The front toes are very slightly bordered with membrane; and the hind toe is small and articulated higher on the tarsus than the front toes. They are not such swift runners as the sandpipers, neither can they glide through tall herbage with the same adroitness as the snipes; but still they are rather clever birds upon their legs. They are also well-winged birds, and have much command of themselves in the air, either in forward flight or in whirling and doubling.

Over the temperate and the cold latitudes, the tringas are pretty generally distributed; and, though they are not so decidedly migrant for long distances in latitudes as many other birds, they seldom summer and winter in exactly the same locality. As is the case with many other birds which are conspicuous enough when not in the breeding season, the breeding places of many of the tringas have not been well ascertained. They are subject to considerable differences of colour too; and this has sometimes caused one species to be described as two. Our limits will permit of our noticing the mere outlines of the British species only.

THE PURRE OR DUNLIN (*T. variabilis*). This bird is well entitled to the epithet *variabilis*, from the great difference between its summer and its winter plumage. It is the "purre" in winter, and the "dunlin" in summer.

The winter dress is the one in which it is most frequently seen on the shores, and it continues there and in that dress for a very considerable portion of the year. In this winter dress, in which it appears on the coast, and especially on the south coast of Britain, for great part of the year, it has the top of the head, the back of the neck, the back, and the scapulars, ashen-grey clouded with brown, and the shafts of the feathers dusky black; the wing-coverts are blackish brown, with the margins grey, and the tips of the larger coverts whitish; the rump and upper coverts of the tail are brown, margined with a lighter shade of the same colour; the middle tail feathers brown, and the lateral ones grey with whitish shafts; the tail is slightly wedge-shaped, the middle feathers being the longest, but the external lateral ones have the broadest webs. The under parts are white, with the exception of the foreneck and breast, which are grey with brown shafts to the feathers. This plumage is, however, not the same at all times of the winter; and it is also paler in very severe winters than in mild and open ones.

In summer, or in that state in which it is the

"dunlin," the upper parts are blackish or black, with red-brown margins to the feathers, and the rump and tail coverts are brownish black; the cheeks, foreneck, and breast, are black, with white margins to the feathers, and the rest of the under part of the body becomes wholly black; the chin is as white as in the winter, and the flanks are also white, but streaked with longitudinal lines of black; the quills and coverts are nearly the same at all seasons. The first plumage of the young birds is intermediate between the winter and the summer plumages of the adults; but it fades into the pale colour in the winter, and regains the dark against the next summer.

The length of these birds is from seven to eight inches, and the stretch of the wings is very nearly double the length; the bill is black, and the feet and toes are dusky green.

In winter they assemble in small parties, following the tide, on the oozy shores and banks of the lower estuaries near the sea. When undisturbed they run rather swiftly, and utter a sort of murmuring note; but when they are alarmed and forced to the wing, they utter a querulous and wailing scream. From the short time that they are absent from our shores, it is not probable that many of them leave the country in the breeding season; though some appear to move northward within the country, and others to the borders of the inland lakes. In the breeding time, however, they are solitary; that is, they are in single pairs, and they are comparatively silent. They have very rude nests, only a little scratch in the dry surface, in which a few vegetable fibres are placed.

PURPLE TRINGA (*T. purpurea*). This is rather a larger bird, rather more than an inch larger in the body, but not larger in the wings, so that it is not quite so well adapted for flight as the other. The bill is longer, harder, and more pointed at the tip; its general colour is a dull dusky red, with the tip and the edges of the mandibles black. The tarsi are shorter in proportion than in the preceding species, and the toes are a little more free to their bases. They are the same dull red as the bill, but the claws, which are quite blunt, are dusky.

The plumage varies with the seasons; and as the winter plumage is that in which it is most commonly seen in Britain, we shall mention it, and notice the changes that take place in the summer. At that season, the head and neck are dusky black; the rest of the upper parts black, with reflections of purple; and the upper part of the back and the scapulars with ash-coloured margins to the feathers. Four feathers in the middle of the tail are of the same colour as the lower part of the back; but the remaining ones are ash colour. The wings are black, with a little white on the tips of the coverts, small white margins to the primary quills, and some of the secondaries nearly white. The under part white, with stripes of black on the breast, sides, and flanks. In summer, the upper part of the breast is grey, and the sides of the same black; the bill and feet also bloom to a bright reddish orange. This species is found on the shores of the Atlantic and the Mediterranean, and on the American side of the former as well as upon the European side. Its nest is rather rare in Britain; and the bird is by no means a very abundant one, even in the winter. It frequents more stony places of the shores than the variable tringa, and its chief food is understood to consist of the small crustacea and mollusca abounding on stony shores.

THE KNOT (*T. canutus*) is a larger bird than either of the preceding species. It is ten inches long, and more than a foot and a half in the expanse of the wings. These birds are fond of soft and fenny shores, and they are scattered over various parts of the coast, both toward the north and the south, but they are not abundant anywhere. They are birds of lonely places, the dreary shores from which the tide retires to a great distance, or the larger marshes near the sea. The upper parts are black in summer, with rust-coloured margins to the feathers; the coverts and quills dusky, the former tipped, and the latter margined, with white; the upper tail-coverts barred with white and dusky; the tail-feathers blackish ash, with very narrow margins of white. The under colours are, rust-red on the breast, and white on the rest, mottled with dusky. In winter, the upper plumage fades to dusky ash, and the under to white, with brown streaks on the sides and flanks.

CURLEW TRINGA (*T. subaquatica*). Bill and tarsi longer in proportion than in the other tringas, and black; the bill considerably arched; the legs bare for some distance above the tarsal joint. In summer the head is dusky ash, the breast reddish brown, the back deep black, with red margins to the feathers. In winter, the forehead, and most of the under part, white; the breast cream colour, and the back dusky. The size about the same as that of the purple tringa, but the habits more aquatic.

THE BUFF-BREADED TRINGA is very rare as a British bird, and its several changes of colour are not known. It is about the same size as the last mentioned species. The *Minute Tringa* and *Tenninck's Tringa* are small species, about six inches long, and both of them are rare in Britain.

There is one other bird, which was once associated with the tringas, under the name of *Tringa pugnax*, and which, though it has very properly been separated from them, we shall notice in this place, as it was omitted under its proper name. That bird is,

THE RUFF (*Machetes pugnax*). Its haunts are analogous to those of the different species of tringa, but in some of its habits it resembles the gallinaceous birds. In the pairing season the males fight desperate battles of gallantry. They are considerably larger than the females; and in the breeding season they have an accession of ornamental feathers, which, notwithstanding their seasonal changes of plumage, is not known among the tringas. This consists of a ruff or mantle of long glossy feathers, which, growing from the neck, fall down as far as the scapulars, something after the fashion of a Spanish mantle. At the same time they acquire tufts of feathers on the ear-coverts, and the face becomes covered with fleshy tubercles of a yellowish red colour. Thus, though the nuptial appendages are different in the details, they display the same exuberance of energy which the males of our common poultry display at the same season. In the form of their bodies they have a considerable resemblance to the tringas, but the bill and the feet are different. The bill is partially flexible only a little way at the base, and the terminal part of it is very compact and hard; the feet also are walking feet, without being particularly adapted to any kind of surfaces; the colours are very variable, not only with the season, but in different individuals. The male is nearly a foot in length, of which the bill occupies one inch. The female is a third less. In their walk, especially the males, they have a sort of

strut, and have the head and neck more elevated than the other marsh birds.

In former times they were very abundant in the fen districts of England, and were among the birds reckoned first-rate dainties for the table. They were known by two names, "ruffs" and "reeves;" the former meaning the male with the ruff of produced feathers, and the latter either the female or the male when the ruff disappears. In those times they were captured in great numbers by the fowlers of the fen countries, and fattened in confinement for the London market, where they were in great demand by the curious in gastronomy. At present the numbers, as is the case with most of the fen birds, are greatly reduced, though those that do come still keep up "the customs of their ancestors."

They are migrants, and make their appearance in the spring, the males always before the females. At this time they are on the best terms possible with each other. They repose quietly in the herbage during the day, and come out to feed during the night, or rather early in the morning and late in the evening. This is the time at which they used to be taken by the fowlers; for, though not in high condition naturally, they feed readily. During this quiet time the ruffs, ear-tufts, and other "signs of the times," wax conspicuous apace, and soon after the natural cause of their warfare comes in the shape of the females.

The moment that these make their appearance, the doughty warriors prepare for deeds of bills—not by squabbling in a sort of private *duello*, where two happen to cross each other in their amorous courses, as is the case with the "ruffs" of mankind, who, like their kindred of the fens, have nothing to do or think of but "sleeping o' days, feasting o' nights, and wooing their dames." They carry on the war in a business-like manner, not for territory, but for glory,—as if they were the people of some happy isle of the sea, proud of being slain in any body's cause for any object, and at their own cost and charge. They are even superior to those self-devoted victims of glory; they fight for what would make the blood of the Pol-Economicus of "the University" curdle like cooling lead, and turn the fervid Lady of anti-matrimonial notoriety into an icicle, not to be thawed by the furnaces of seven thousand lovers: they fight in order that each may be—the father of a family! They do not come to the scene of battle as mercenaries, or any way in the train of a leader, as is the case in the un-gallant wars of the human race; each comes on, and for his own proper interest, to win the surrounding patch of marsh and the favourite, in like manner as barn-door cocks wage fierce battle for the dunghill and the dame. There is no herald to whet the stomachs of the combatants, as there was when whilom the bibliopoles of London are said to have contended at the may-pole in the Strand for the honour of polluting the public ear with the productions of Mrs. Centlivre—

"His be yeon Juno, of enormous size,
With cow-like udders, and with ox-like eyes;"

neither is any of the present file likely to receive even the *vasa preciosa* for his private delectation—
Eheu! tempora mutantur.

"No heavy lord now hangs at every wet."

Still, the wars of the ruffs are faithful to the observances of the olden time, and admit not of the

slightest innovation. One ascends the "hill," and raises the cry of defiance, upon which forth rush the doughty birds, and the battle rages the live-long day, or till one has been conqueror, and leads off the dame to rushy bowers of sweetest love. The battle is renewed, with continuation of days, until they are paired and pacified; but the fate of the vanquished in the last and single combat is not known, whether he takes monastic vows, subject to fracture, *more monachi*, or goes off in purling streams, the learned have not decided. The wars of the ruffs are, however, very curious matters, and matters which cannot be explained upon any of our common theories of the conduct of animals, and the reasons which we affect to assign for that conduct.

The nests for which all this battling is carried on are but rude structures. They are formed of a few withered stalks, in the thick tufts of herbage, which stud the marshes. The eggs are four in number, pale olive brown in the ground colour, and spotted with darker brown. The young are produced about the longest day. It does not appear that the males give themselves any trouble about the females, the nests, or the young. During the incubation they bill as before, and battles are fought in the early parts of it; but as it proceeds these wear off, and by the time that the young break the shell the males merely show themselves. Soon after this they leave the females to provide for the young as they best can, and go into retirement for the purpose of changing their dress. The mantle, the ear-tufts, the caruncles on the face, and all the other insignia of the period of pugnacity, are thrown off, and the ere-while warriors come out of the places of their temporary retirement in plain apparel, and as gentle and peaceable as lambs. The produced feathers on the males of these birds do not belong to any particular moult; they come after the time of what may be considered the spring moult, and they are gone before the autumnal one, so that they are in an especial manner insignia of the breeding season. They are so varied in their colours, between nearly black and nearly white, that it is impossible to mention their tints. Their lustre is almost equally a puzzle; it is not metallic or vitreous, or any other that we could name; it is the bloom on the nuptial plumage of the ruff, and as such, it has no counterpart in nature by means of which it can be explained to those who have not seen it. After the moult the plumage of the birds is of a very sober character. Besides the capture of the males upon their appearance in the spring, there used to be a more extensive and indiscriminate capture in the month of September, at which males, females, and young birds of the year, were equally captured. It appears that the greater number migrate in the winter, but there are some stragglers that remain in the country.

TRIOPTERIS (Linnæus). A genus of twining shrubs, natives of the West Indies. The species belong to the tenth class of Linnæus, and to the order *Malpighiaceæ* of Jussieu. They are easily grown and increased in the stoves.

TRIPHASIA (Loureira). A genus of one species of plants found in China, and specifically called *Aurantiola*, the little orange. The flowers are pentandrous, and the plant belongs to the order it so much resembles, viz. *Aurantiacæ*. It was called *Limonia trifoliata* by Willdenow. It does not thrive with much moisture, but with care may be increased by cuttings.

TRIPLARIS (Linnæus). A forest tree of South America, bearing dioecious flowers, and belonging to the natural order *Polygonacæ*. Notwithstanding its natural bulk it may be kept in a dwarfed state and propagated in our hothouses, with the ordinary treatment of plants from the same quarter of the world.

TRIPLAX (Fabricius). A genus of coleopterous insects, belonging to the group of which *Erolytus* is the typical genus, and distinguished by the ovate form of the body, with the last joint of the maxillary palpi strongly securiform; the maxillæ have the internal lobe membranous, with a small tooth at the tip. These are insects of small size, found in boleti and fungi; they have the head and thorax generally of a red colour, with the elytra blue or black. The genus *Tritoma* (Fabricius) is closely allied to the preceding, differing chiefly in the rounded form of the body. The type is the *Tritoma bipustulatum* (Olivier), which is found in similar situations with *Triplax*. It is small, and of a shining black colour, with a large red humeral spot.

TRISTANIA (Dr. R. Brown). A genus of New Holland evergreen shrubs, bearing polyadelphous flowers, and belonging to the natural order *Myrtacæ*. The species are desirable greenhouse plants, thrive in light loam and heath-mould, and may be propagated by cuttings.

TRITICUM (Linnæus). One of the most important of all the *Gramineæ* to European society, as well as to every other part of the world suitable to its culture. As a bread-corn wheat is superior to every other kind of grain. There are several species described and hundreds of varieties. A few only of the best varieties of winter and spring sorts are cultivated; the great majority are as suitable for the British climate, and even the favourite varieties are so much mixed that a pure sample of any one particular sort is not to be had. It is with wheat as with almost all other plants; the best varieties being accidental productions, are only for a longer or shorter time thrifty in any one locality. After a few years they degenerate, and then require to be succeeded by another kind, and, if convenient, from some distant quarter.

TRITOMA (Ker). A genus of herbaceous perennials, natives of the Cape of Good Hope. The flowers are hexandrous, and the genus is associated with the *Hemerocallidæ*. They are half-hardy plants, and bear our winters with a very slight covering. They flower early in the spring, if kept safe from frost.

TRITONIA (Ker). A genus of handsome flowering South African bulbs, belonging to the third class of Linnæus, and to the natural order *Tridacæ*. The species, of which there are above twenty, require similar treatment and soil with other Cape bulbs, that is, potted in light soil in October, and when rooted fully, they may be removed to the greenhouse to bloom.

TRIUMFETTA (Linnæus). A genus of tropical undershrubs and annuals, bearing dodecandrous flowers, and belonging to the order *Tiliacæ*. The species already in our collections are easily grown and increased by seed, which they yield plentifully.

TROCHILIUM (Scopoli). A genus of lepidopterous insects belonging to the family *Ægeriæ*, having the body thick, with a small caudal tuft; the wings diaphanous, and the antennæ short and stout. There are two British species, namely, *T. opiforme*,

the hornet moth, and *T. bombyciforme*, Hb.; (*Crabroniforme*, Lewin, the lunar hornet moth), see *ÆGERIDÆ*. These insects reside in the larva state in the stems of the broad-leaved willows (*Salix caprea*), which they longitudinally perforate in various directions. These larvæ are fleshy grubs with a scaly head, six short legs, and eight fleshy prolegs. An interesting account of the habits of this insect is published in the third volume of the Linnæan Transactions, and more recently by the Rev. W. T. Bree in the new and improved series of the Magazine of Natural History. These larvæ enter the stems near the roots, eating their way upwards for several inches, sometimes to the length of a foot or more. "Being an internal feeder, the caterpillar of course is only to be found by cutting into and opening the stems of the willow in which it is inclosed, finding there both food and lodging. *Salix caprea* abounds in our coppices near Allesley, Warwickshire, and forms a useful and rapid-growing underwood. When the periodical falls take place, I have observed that scarcely a single willow-wand is cut down that does not exhibit proofs of the ravages of this insect; sometimes three or four, or even five separate perforations occur in the same stem. To the woodmen our elegant sphinx must be regarded as in some degree an injurious insect. The wood of *Salix caprea* is with us usually either sold to the rake-maker, for the purpose of being worked up into rake-teeth, &c., or converted into what are here called flakes, *i. e.*, hurdles made of split stuff nailed together, in contradistinction to the common hurdle, which is formed of round wood twisted and plaited together without the help of nails. The lower, and consequently the thickest portion of each willow rod, to the length of five or six inches, or occasionally a foot or more, is spoiled by the perforations of the larva, and rendered unavailable to the above purposes." The writer hereof has met with this handsome species in the osier beds on the south side of the Hammersmith Suspension Bridge. (See Trans. Ent. Soc., Part III.)

TROGIDÆ (MacLeay). A family of coleopterous insects, of small extent and obscure colours, separated from the genus *Scarabæus* (see *LAMELLICORNES*), distinguished by having the antennæ ten-jointed, the basal joint large and hirsute; the palpi are short; the maxilla toothed; the body rugose and tuberculated, or fasciculated on the upper side; the thorax short and transverse, with the anterior angles advanced in front. There are only two British genera, *Ægialia* and *Trox*, the former globose and smooth, the latter more ovate and rugose. The type of the genus *Trox* (of which there are four British species) is the *Scarabæus sabulosus*, Linnæus. They are generally found in sand-pits and similar situations.

TROGOSITA (Fabricius). A genus of coleopterous insects, belonging to the family *Cucujidæ*, having the mandibles exposed and robust, but shorter than the head; the body narrow and depressed; the antennæ shorter than the thorax, and terminated by a compressed three or four-jointed mass; the labium is entire, and the maxilla have one lobe. The type is the *Tenebrio mauritanicus*, Linnæus, an insect about one-third of an inch long, of a pitchy black colour. It feeds upon bread, flour, &c., and is occasionally taken beneath the bark of trees. Its larva is very injurious in Provence, where it is known under the name of the *Cadelle*. This is the only British species.

The exotic ones are rather numerous, and some of them very splendidly coloured.

TROLLIUS (Linnæus). A genus of showy flowering herbs, found in the north of Europe and America. The flowers are polyandrous, and belong to *Ranunculaceæ*. The *T. Europæus* is a native of Britain, and called the globe-flower division.

TROPÆOLEÆ. A natural order, containing only one genus, to which the well-known *Tropæolum majus*, or Indian cress of our gardens, belongs. This order comes near to *Geraniaceæ*, but differs in having separate stamens, and in the number of petals. There are eleven species described, all natives of Peru. *T. pentaphyllum* is used as an antiscorbutic; the flowers of both *T. majus* and *T. minus* are an ingredient in salads, and their fruit are used as capers, or as a pickle.

TROPHIS (Linnæus). A genus of two West Indian trees, called there Ramoon-trees. The flowers are diœcious, and the genus belongs to *Thymelææ*. The species are free-growing plants in our stoves, and are increased by cuttings.

TRUXALIS (Fabricius; *GRYLLUS ACRIDA*, Linnæus). A genus of exotic orthopterous insects, belonging to the family *Locustidæ*, distinguished at once by the elongated form of the head, having the eyes placed near the extremity of the long and slender pyramidal front, with the mouth very low, and appearing to be placed at the breast, and by the prismatic or ensiform antennæ. The species are of considerable size, and often elegantly varied with pink, green, purple, &c., especially on the wings. They are inhabitants of the warmer climates of the globe.

TRYPOXYLON (Latreille; *APRUS*, Jurine). A genus of hymenopterous insects, belonging to the family *Crabronidæ*, and distinguished by the very elongated form of the abdomen, which is gradually narrowed into a peduncle at the base. The mandibles are curved and without teeth; the upper wings have two submarginal cells, each receiving a recurrent nerve. The type is the *Sphæx figulus*, Linnæus, a very common insect in gardens, &c., of a black colour, with the margins of the abdominal segments and the face silvery. The female makes use of the old burrows of other insects, which she discovers in stumps of wood, &c., and in which she buries small spiders as the food of her offspring, closing up the hole with moistened earth. (See Shuckard's Monograph of the British Fossores, and the Trans. Entomol. Soc., Vol. I., Part III., for a memoir upon the habits of this insect.)

TUBEROSA is the *Polianthes tuberosa* of Linnæus, an East Indian genus, celebrated for the powerful fragrance of its flowers. The tubers are annually imported into this country from Italy. These are potted in sandy loam and peat-earth, placed in a hot-bed to bring them forward to flower in the autumn, and then are placed in the greenhouse, or entrance-halls of dwelling-houses, as graceful ornaments.

TULIPACEÆ. A natural order of beautiful flowering plants, natives of temperate climates, and containing eight genera, of which there are one hundred and twelve species already described. The genera are, *Yucca*, *Tulipa*, *Fritillaria*, *Cyclobothra*, *Calochortus*, *Lilium*, *Gloriosa*, and *Erythronium*, all of which, except the first, have been previously described under the proper generic names. But the

general character of *Tulipaceæ* is stated thus:—"Specious hexapetaloid hexandrous endogenæ, with introrse anthers, superior germen, connate styles, three-celled capsular fruit, with many albuminous seeds, having spongy testæ."

TULIP TREE is the *Liriodendron tulipifera* of Linnæus—ornamental trees, natives of North America, and long introduced into our ornamental plantations. They are raised from seeds imported from America. The seeds are generally two years in the ground before the seedlings appear.

TURNERACEÆ. A natural order, comprising only one genus, unless *Piriqueta* be considered a distinct genus, which is doubtful. The species have alternate leaves, and yellow axillary flowers, resembling those of *Helianthemum*. The *Turneria* are chiefly interesting for their relations to collateral groups.

TURNSTONE. See **STREPSILAS**.

TURRÆA (Linnæus). A genus of trees, found in India, having decandrous flowers, and belonging to the order *Meliaceæ*. These timber-trees submit to be cramped in pots of light loamy earth, thrive in the stove, and may be propagated by cuttings.

TURTLE. See **CHELONIA** and **REPTILE**.

TURTLE-DOVE. See **PIGION**.

TUSSILAGO (Linnæus). A genus of broad-leaved herbaceous plants, mostly natives of northern Europe. Four of the species are British, and known by the name of colt's-foot. The flowers are composite, appearing before the leaves. Their properties, particularly *T. farfara*, are medicinal, but less in repute now than formerly. The same plant is a plague to farmers on clayey soils.

TYCHUS (Leach). A genus of coleopterous insects, belonging to the family *Psephenidae*, distinguished by having the fifth joint of the antennæ large and knot-like, especially in the males. Type, *Tychus niger*, Leach, an insect of minute size, found in damp moss in the winter.

TYLOPHORA (Dr. R. Brown). A genus of climbers from New Holland and India. They belong to the fifth class of Linnæan botany, and natural order *Asclepiadææ*. The species are easily grown and propagated.

TYPHÆUS (Leach). A genus of coleopterous insects, belonging to the family *Geotrupidæ*, and chiefly distinguished by the males being furnished with horns upon the head and thorax. The only British species is the *Typhæus vulgaris* (*Scarabæus typhæus*, Linnæus), a very abundant species, found in and about the excrement of horses and cows in sandy places. It is known to collectors under the name of the bull-comber.

TYROPHAGA (Kirby). The cheese-maggot. See **PIOPHILA** and **CHEESE-HOPPER**.

TYPHINÆ. A natural order of aquatic plants, containing only two genera, namely, *Typha* and *Sparganium*, both natives of European ponds, sluggish rivers, and ditches. The *Typhas* are conspicuous seed-like plants, and called in English cat's-tail.

ULEX (Linnæus). A genus, of four species, of one of our commonest plants on English wastes. Furze, though a wild vagrant, is not without beauty; its numerous flowers, appearing more or less at all seasons, compensate for the rigid character of the shrub itself. Nor is it wanting in usefulness. It is a wholesome fodder for cattle when duly prepared;

NAT. HIST.—VOL. III.

and, as fuel for the brick-maker, rural brewers, and bakers, it is an excellent substitute for more costly fuel. In some countries furze is extensively cultivated, and yields as great a profit in a given term of years as if the land were cultivated for the growth of corn. Hedges are formed of it, and it is, moreover, an excellent cover for game. The flowers are monadelphous, and, as its fruit is a pod, it belongs to the order *Leguminosæ*. The Irish and double-blossomed furze are now admitted into the flower-garden.

ULMACEÆ. A natural order, containing three genera, namely, *Planera*, *Ulmus*, and *Celtis*. Of these there are nearly forty species described, most of which are also in cultivation. The common elm is the type of the order, and which, with its congeners, have the following generic character:—They are trees or shrubs, with knotless or jointless branches, alternate, simple, petiolate, scabrous, serrate leaves, the stipules free and often deciduous; the flowers are united, being collected into sub-amentiform clusters; the calyx is free, campanulate, and cleft at the edge, with an imbricate aestivation; the stamens are five in number, all fertile, and exserted from the base of the calyx; the anthers are free and two-celled; the ovary free, and also two-celled; stigmata two and distinct; the fruit is two-celled, membranous, or drupaceous; the seed solitary, pendulous, and without albumen.

The elms, it is well known, are large handsome trees, but their timber is of far less value than either oak, chestnut, or pine. Though tough and strong, it is too liable to warp and shriek. It is mostly used by wheelwrights and coffin-makers. Elm leaves formed a large proportion of the "British leaf," or "herb," intended to be sold as Chinese tea, but seized and burnt by the officers of excise.

The *Celtis*, or nettle-trees, though exotics, arrive at considerable bulk in our plantations, and may now be considered naturalised foresters.

The *Planeras* are North American deciduous shrubs, discovered and named by Michaux. They thrive in our shrubberies, and are propagated by layers.

UMBELLIFERÆ. One of the most important and most extensive natural orders; important, as embracing the carrot, parsnep, and celery, as dietetic plants in Europe; and the arracacha in South America; and containing, as useful medicinal plants, the galbanum, opopanax, and assafœtidæ. The order is divided by botanists into three sub-orders, namely, *Orthospermeæ*, which is separated into eleven tribes; *Campylospermeæ*, containing three tribes; and *Colospermeæ*, comprising one tribe. The generic character is expressed thus:—apopetalous, angiospermous, dichlamydeous dicotyledons, the petals narrow at the base, and involute; the stamens five, exserted from an epigynous disk; the carpels didymous and inferior, each one-celled; the ovules solitary, and the seeds albuminous; the leaves alternate, and the inflorescence umbellate. There are one hundred and one genera in this order, and above five hundred and seventy species already described; many of the species are inconspicuous worthless weeds, and often found in watery places.

UNAU—Two-toed Sloth (*Bradypus didactylus*). The general characters and habits of the sloths have been so fully noticed in the article **AI** and the article **BRADYPUS**, that it will be unnecessary to do any thing further here than simply to point out the cha-

FFF

acters of this species, or rather the sub-genus, for the animal differs sufficiently from the *Ai* to entitle it to that distinction. The unau has only two claws on the fore feet, though it has three on the hind ones. The tail is very short, consisting of only three vertebrae, and wholly concealed in the hair. The fore legs are not so long as in the *ai*, and they bear a proportion to the hind legs of six to five. The bones of the extremities are not so completely soldered together as in the *ai*, the first phalanges of the toes are free, though always soldered to the sesamoides. The claws are one-half shorter in proportion than those of the other. It is larger than the *ai*, its head is more elongated, its forehead less round and prominent, and its facial line more oblique. Its covering consists of rough hairs, thicker and coarser than those of the *ai*, but not quite so long and shaggy. They are partly brown and partly white, the former predominating on the back, and the latter on the under part. This mixture, which is not in spots but in single hairs, gives it a peculiar tint of grey, which appears deeper where the brown hairs predominate, which they especially do on the upper part of the neck, on the former of which the hairs are long, and produce a sort of mane. There are also very strong hairs on the thighs, and the hair on the fore arms is reversed. The canines are much larger and more conspicuous than in the *ai*, and they are separated from the cheek-teeth by a ridge of the jawbone. The proportions may be judged of from the statement that, in a specimen whose body is two feet, the head is about five inches long, the inner claw on the fore foot two inches, and that on the hind foot an inch and three quarters. The claws on the hind feet are longer than those on the fore ones, and the intermediate is the longest of three. The claws are in reality hoofs, embracing the whole extremities of the toes, as in the hoofed animals, and therefore are regular parts of the extremities as organs of locomotion.

Though this animal is not so utterly helpless upon the ground as the *ai*, it is yet but a very slow walker, and does not get on at a more rapid rate than a tortoise. It is much more at home in climbing, and can contrive to reach the top of a tall tree in a moderate length of time. Its favourable position, like that of the otter, is suspending itself by the feet with the back undermost; and it can thus suspend itself by three feet, and use the remaining one in feeding. It sleeps suspended.

All its senses, and indeed the whole of its vital energies, are of a very low and imperfect character. Of its hearing we know little, but it is not much startled by sounds. Its sense of smell is obtuse, and it sees badly in a strong light. Altogether it is much more a passive than an active animal. It can endure hunger for a long time, and is not much affected by blows, or even by wounds. All its qualities are in fact more of a passive than of an active nature, and it lives much more by its power of enduring whatever may be going on around it, than by its own activity, exertion, or resource of any kind.

It is by no means rare in the thick and close forests of South America; indeed it appears to be much more abundant, at least in some places, than the three-toed sloth; and, though it is not perhaps equal to that animal in power of perambulating the upper parts of the trees in the thick forest with the back undermost, it can more readily descend and again remount when it comes to an opening.

Of the duration of life, either in it or in its congener, we know nothing; but the numbers are considerable as compared with the productive powers, which consist of but one at a birth, which one attaches itself to the mother by means of its claws, and clings to her in all her climbings among the trees. This carrying the young attached to the body bears some resemblance to the marsupialia with a perfect pouch, only the mode of carrying is varied to suit the habit. The young, attached in any way to the belly, would be very inconvenient for the mother, and very unsafe for the young, in an animal which has the back undermost, and the belly in contact with those branches which form its pathway in the forest. The back, on the other hand, is equally safe for both. We must not wonder at this; for the unau still supports the young in that which is her own position of stability, namely, with the back undermost; and as the structure of the young one is the same, the back undermost is the position of stability for it also. The sloths of whatever species are reversed animals in their position of action as compared with ordinary animals; and therefore we must look upon all their performances the other way. In an upright animal, the young are most safe riding upon the upward back of the mother; but in those reversed animals, they are most safe in clinging to the downward back.

What may have been the state of South America at the time when the mighty animals of the sloth family were alive, or what may have been the precise scene and mode of their action, it is impossible for us to know; but we may with the greatest certainty and safety conclude that it must have then been a rough state of things. That there has been no great geological revolution in that part of the world, since the megatherium fed in some way upon some vegetable, we may be assured; for the remains of the animal have been found in the soft deposit of La Plata, without a single bone displaced or disjoined; and thus there must have been a common progress of nature in changing the country, from the time of the megatherium to that of the *ai* and the unau. Along with them, or with either of them, there could dwell no sprightly quadruped of large size feeding upon vegetables; for the remains of the forests are of such a character that they afford neither food nor footing for any such. This leads us to conclude that there must have been rather a rough state of things at that time, and that, on the part of the mammalia, the power of suffering must have far exceeded that of acting. The great bones of the megatherium are obviously formed for endurance, not for activity; and the probability is, that it may have been a still slower animal than the present sloths.

There is one curious point in the progressive zoology of South America; and that is the wonderful productiveness and prosperity of the horse and ox in that country. That there is not a vestige of either of them as having existed there before their introduction subsequent to the discovery of the country by Columbus and his followers, every body knows; and yet they have bred and multiplied there in wild nature, faster than they have done in the eastern continent, or in North America, by all the arts of the breeder. This is undeniable, and yet it seems somewhat strange. Experience has shown that the plains of South America, every where to the southward of the great tropical parts, where the sloths now inhabit, are the places of the earth's surface which are the

very best adapted for cattle. The cattle were not there until they were artificially introduced by man. Is this an anomaly in nature? Is it an instance of imperfection of the system, one where the state of the country was the very best adapted for certain animals, and yet nature did not provide these animals, and thus allowed her own bounty to run to waste?

This is a very important question, and one which involves far more than we would at first suppose. It will be most readily understood by propounding another question: was the discovery of America by Columbus, and the extension of that discovery by his followers, a work entirely originating with man, or was it part of that grand system of the economy of the earth's surface, of which man can understand and know only a very little? We cannot by possibility suppose that these things took place without the knowledge of the Omniscient Ruler of the system of things, or in opposition to the laws which He has ordained for the government of our planet; but the field which this question opens is much too wide for our investigation; and therefore we leave it to the consideration of the reader, for the stimulating of whose inquiry we have merely thrown it out as a hint.

UNICORN of the ancients. See the article ANTELOPE, species *Abu-harbo*.

URANOSCOPUS — Star-gazer. A genus of spinous-finned fishes which belong to the perch family, and to that division of them that lurk in the mud or lie at the bottom of the water, in order to seize their prey as it passes over them; they are in general armed with strong and sharp spines upon some part of their bodies, by means of which they can inflict severe wounds; but whether they employ these in the capture of their prey, or merely as defences against the predatory fishes, such as the rays and ground sharks, which have the mouth on the under side, has not been ascertained.

Of course the star-gazers, like all other bottom fishes, have the abdominal fins jugular or under the throat, in advance of the pectorals. They have the head of a cubical form, with the eyes on the top (hence the name); they have the mouth cleft vertically, the operculum toothed in the under side, a strong spine on each shoulder, and six rays in the gills. They have within the mouth a sort of filament which they are said to put out, as a lure to small fishes, as they lurk in the mud ready to receive the dupes into their capacious mouths. They are found in the warm seas. One, the *U. scaber* of the Mediterranean, is a shapeless fish, of a greyish-brown colour with white spots, and having the spinous part of the dorsal separated from the soft part. Others have them joined. These fishes, shapeless as they are, are eatable.

URANIA (Fabricius). A genus of very singular and beautiful exotic lepidopterous insects, placed by Latreille amongst the butterflies, but evidently forming a distinct family; the antennæ are filiform with the tips setaceous; the palpi are elongated, with the last joint naked; the hind wings are tailed. Mr. MacLeay has published an interesting memoir on the genus in the Zoological Society's Transactions, detailing the natural history and habits of a West Indian species. M. Sganzin has also published some observations at variance with those of MacLeay, in the Transactions of the French Entomological Society. The genus seems most naturally to connect the but-

terflies with the *Hesperis phinges*, the habits of the perfect insects being diurnal, the flight being in the hottest sunshine.

URTICA (Linnæus). A well known genus of herbs and undershrubs, found in every inhabited part of the world, and in English lists known as nettles. The flowers are monœcious, and the genus belongs to the natural order to which it gives a title, namely,

URTICEÆ. A natural order containing twenty-four genera, of which there are above two hundred species. It contains plants of very different aspect, and of very different qualities. Worthless weeds and the most useful fruits, poisonous and sanative, ugly and graceful plants, are here united; and yet there is a similarity, especially in their fibrous constituents, which connect the whole. The opponents of the Jussieuan system have fixed on this order as a decisive proof of the incongruity of the whole natural system; but their opposition is gradually subsiding, though it cannot be expected that difference of opinion on Jussieu's scheme will entirely cease until the whole is re-arranged.

There are two circumstances belonging to the history of the common nettle (*U. dioica*) worthy of notice. The first is that of the pollen being discharged from the anthers in jets like the smoke from a pistol; and secondly, that the nettle is never seen far from the habitations of man.

VACCINIÆ. A natural order including only two genera, namely, *Vaccinium* and *Oxycoccus*. Of these there are fifty-six species already described, and are natives of North America, Europe, and Asia. The *O. macrocarpus* furnishes the cranberries sent from North America, and the *O. palustris* those of Europe. *V. myrtillus* is the well known whortleberry. The order consists of shrubby plants, with aqueous juices, round or angled stems and branches; alternate simple leaves; the petioles short and without stipules; the inflorescence is solitary or racemose, the flowers regular and united; the tube of the calyx is adnate to the germen, from four to six toothed, or entire; the corolla epigynous; the stamens in one series, and borne on an epigynous disk; filaments free, anthers terminal and prolonged into horns; the germen is inferior, surmounted by a torus, which bears both the corolla and stamens; the fruit is a berry, four or five-celled, few or many seeded. This order is now merged in *Eriaceæ*.

VALERIANÆ. Containing five genera, and of these above fifty species; the stems are somewhat jointed, the leaves opposite and variable in form; the inflorescence in terminal, and is cymose or corymbiform panicles; the flowers are united, and either white, pink, or blue, seldom yellow or purple; the tube of the calyx is close to the germen, the limb toothed or cleft; the corolla epigynous, and also cleft; stamens five or less, borne on the tube of the calyx, the filaments free, anthers ovate and incumbent; the germen is formed of three carpels, the style filiform, and the stigmas free or concrete; the fruit is capsular, dry, and induricent.

The valerians are mostly ornamental, the leaves generally esculent, and used as salad; instance, *V. olitoria*, the lamb's-lettuce; the roots of the perennial species are aromatic, and highly stimulating. The natives of India employ the roots of *V. jatamansi* as a perfume; it forming the spikenard of the ancients. The species are all easy of cultivation

in the open ground, and increased by division or seeds.

VALLISNERIA (Linnæus). A genus of Italian and New Holland aquatics, of very curious character. The flowers are dioecious, and belong to *Hydrocharideæ*. The European species grow in Italian ditches of considerable depth. The female flowers are borne on long spiral foot-stalks, and which rise and float on the surface and there expand. The male flowers are produced on a separate, and often a distant plant, and on very short foot-stalks; but when these are nearly ready to bloom, they are detached from their mother plant, and, ascending to the surface, float about among the female flowers, where impregnation takes place. The females, so soon as this takes place, again shrink to the bottom to perfect the seed. The late Mr. Sweet was of opinion, that these plants might be grown in deep ponds in this country.

VANESSA (Fabricius). A very extensive genus of lepidopterous insects, belonging to the section *Diurna*, or butterflies, and family *Nymphalidæ*, having the antennæ terminated in a short abrupt club; the wings are angulated, the larvæ very spinose, and the chrysalis suspended by the tail without any girth round the middle of the body. In this genus are comprised some of our most splendid British butterflies; the red admiral (*V. Atalanta*); the Camberwell beauty (*V. antiopa*); the peacock (*V. io*); the large and small tortoise-shells (*V. polychloros* and *Urtica*); and the comina (*V. C. album*), all belong to this genus. They are, for the most part, of such common occurrence, as to render minute description unnecessary.

VANILLA (Swartz). A genus of climbing orchideous plants, natives of tropical America. One of these is the old *Epidendron vanilla* of Linnæus, the roots of which are used for flavouring chocolate, and also for perfuming snuff. They are grown in damp moss in our stoves, and require a rough barked stump, or a tree, or other support to climb upon.

VELIA (Latreille). A genus of water bugs (*Hydrometridæ*), having the legs formed for skimming along the surface of water, of moderate length, and placed at equal distances from each other. See article *INSECT*, vol. ii., p. 842, figures 44, 45, for representations of these insects.

VERATRUM (Linnæus). A remarkable genus of hardy herbaceous plants, bearing polygamous flowers, and belonging to the natural order *Melanthaceæ*. From the beauty of their foliage, and stately spike of flowers, the species are worthy a place in every flower-garden. They are increased by division or by seeds, which must be sown as soon as they are ripe.

VERBASCUM (Linnæus). A numerous genus of biennial and perennial herbs, mostly natives of Europe. The flowers are pentandrous, and the genus belongs to *Solanecæ*. The mulleins are well known British hedge plants, though some of them are admitted into the garden.

VERBENA (Linnæus). A genus of annual, biennial, and perennial herbs, chiefly natives of America; and their character is so peculiar, as to be taken as the type of the order

VERBENACEÆ. Containing twenty-nine genera, and two hundred and seventeen species already described in books. It is an order composed of plants of very various habits, lofty trees, and diminutive herbs, bearing conspicuous or colourless flowers, and with ample or attenuated foliage. The inflo-

rescence is solitary or aggregate, spicate, capitulate, or corymbiform, and both irregular and united: the calyx is free, tubular, with a divided limb, and persistent; the corolla is hypogynous, tubular, with a five-lobed limb, more or less irregular, and deciduous; the stamens four or five, didynamous, sometimes only two exerted from the tube of the corolla, and alternate with its lobes; filaments are free, the anthers adnate, two-celled, and bursting lengthwise by chinks; the germen is free, and formed of two connate carpels; the style one, and the stigma scarcely divided. The vervain was a sacred plant, and in the Druidical superstitions, was regarded with reverence. To ancient superstitions is still owing its repute as a medicine, as it was long esteemed as a potent ingredient in love philtres. It is slightly bitter and astringent; but its influence over disease or passion is merely imaginary. *V. Lamberti*, and *V. aubletia*, are ornamental plants; but the most useful in the order is the famous *Tectona Indica*, or teak-tree of the oriental forests. Its trunk is sometimes seen above two hundred feet high, especially about Malacca and the neighbouring islands; and for ship-building is almost equal to the oak.

VERBESINA (Linnæus). A genus of shrubs and herbaceous perennials, mostly natives of central America. Their flowers are mostly yellow, and belong to *Compositæ*. Different species of *Verbesina*, according to the country they come from, require the stove or greenhouse, and some of them are hardy, grow tall, and take their place in the shrubbery.

VESPA (Linnæus); **VESPIDÆ**, (Leach). The wasp family. See *WASP*. The hornet is also one of the large species of this genus, being systematically under the name of *Vespa crabro*.

VIBURNUM (Linnæus). A genus of evergreen and deciduous shrubs, natives of both North America and Europe. They belong to the fifth class of Linnean botany, and to the natural order *Caprifoliaceæ*. The species are almost all ornamental shrubs, some of them decidedly so, as the *V. tinus*, *laurustine*, and the *V. opulus*, the guelder-rose. The *V. rugosum*, and the *V. odoratissimum*, are greenhouse species, and handsome plants. The hardy sorts are chiefly propagated by layers, the more tender sorts by cuttings.

VICIA (Tournefort). A numerous genus of climbing annual and perennial herbs, mostly natives of Europe. The flowers are diadelphous, and the genus belongs to *Leguminosæ*. Vetch is the common name of this genus of plants. Several of them are useful agricultural objects, being in most seasons the earliest green forage that can be cut for cattle.

VIOLA (Tournefort). This favourite genus gives a title to Jussieu's natural order of

VIOLARICÆ, and which comprises twelve genera, and one hundred and thirty-five species. The greater part are hardy herbaceous plants, some of which are attractive for their perfume, others for their varied colours, and all for their neatness. The generic character of *Violaricæ* is expressed briefly thus: apetalous, angiospermous, dicotyledous, with the sepals imbricate, and the petals obliquely convolute in æstivation; the stamens equalling the petals in number (five); the filaments elongated beyond the anthers, style one and undivided; ovary one-celled, with narrow placenta, opening laterally; the seeds albuminous, the embryo erect, and the leaves furnished with stipules.

It is said that there are some suffrutescent violets in intertropical countries which have not yet been introduced into this country; but all the hardy sorts have been long admitted in the flower-garden for placing on rock-work and shady borders. The *V. tricolor* is now cultivated under the name of pansies, or heartsease, most extensively by professional florists, who have originated numerous varieties, excelling in size, colour, and variety, all that were before known. They are all readily increased by parting the root, or by seed.

VIPER (*Vipera*). A genus or rather family of poisonous serpents, having poison fangs unaccompanied by other teeth. They occupy the same place in the eastern continent that the *Crotali* (rattlesnakes and triangular-headed snakes) occupy in America, and with them include the whole of the land *Ophidi* which have poison fangs; the other poisonous serpents have common teeth along with their poison fangs, and are all aquatic in their habits, constituting what is called the *Hydra* family.

The vipers of the eastern continent are more numerous and varied in their species than the *Crotali* of the western; but taking them on the whole, they are not so formidable in their appearance or so deadly in their venom. There are, however, exceptions to this, depending partly on the species and partly on the warmth of the climate and the season; and in those extreme cases wounds inflicted by any small ones are attended with the most fatal consequences.

The vipers occupy the same place, both in the system and on the globe, among the poisonous serpents, which is occupied by the colubers, among the true serpents which are not poisonous; and as they have the plates under the tail double as well as the colubers, they have been confounded together, and the poison of the vipers has been imputed to the others which are certainly not poisonous. This confusion of two sections of animals so very different, as those are in the character which gives them their chief interest with mankind, has often been productive of double mistakes. The harmless colubers have been persecuted as if in possession of deadly venom, and people have been terrified at them; on the other hand, some have, from experience of the harmless nature of the colubers, been led to tamper with the adders, and have paid dearly for their temerity. The true criterion as to whether a serpent is or is not poisonous, is the presence or the absence of the poison fangs.

The poisonous ones are also less lively in their motions, as the few serpents which are harmless are less lively than the snakes; the principal distinctions are, however, to be sought in the appearance of the species. There is one character which prevents the vipers from being confounded with those poisonous representatives in the west, the crotali. The last have second or posterior lappets to the nostrils, and the vipers have not. Practically this distinction is of very little consequence, as the two are never found in the same places, and as, though they were, they are equally to be avoided.

The viper family, or rather tribe, admits of subdivision into four sections; the first having the scales on the head of nearly the same size and character as those on the upper part of the body, and this is a distinction between them and the non-venomous colubers. The second have large plates on the top of the head, resembling those of the colubers, but they

have the poison fangs apart like the former; the third, the tail flattened like an oar for swimming, or otherwise different from the typical vipers; the fourth have the poison fangs in the same row with other maxillary teeth, only larger in size, and the scales on the belly and tail like those of the *boa* and *crotalus*, but as they do not inhabit the same part of the world as either of these, there is no danger of confounding them in wild nature. They make in all ten genera, or subgenera, in Cuvier's arrangement.

VIPERA—Vipers, properly so called, or those which have the scales on the head similar to those on the back; but some even of these have differences in this respect.

Common Viper (*V. berus*). This is the only poisonous serpent which occurs in Britain, and it is not very common or very dangerous, except in very dry and warm parts of the country, and during the hot season. Being the only British reptile whose bite is in the least to be dreaded, we shall be more particular in our notice of it, but it seems subject to some varieties of colour. Its length is from a foot and a half to two feet, and its greatest diameter in the latter case about one inch. The general colour on the upper part is brown or russet, but in some instances it is ash-grey. It is marked with an irregular zig-zag black line along the back, and with a row of black spots upon each flank; the belly is generally slate-grey, and covered with plates, varying in number from one hundred and forty-four to one hundred and seventy-seven; the plates on the tail are still more variable in number, being sometimes not more than twenty-nine, and in other instances as many as sixty-eight; the head is blunt and truncated in front, broader posteriorly than the neck and anterior part of the body, depressed on the tip, and a little heart-shaped; the top of the head is covered by small granulated scales, and there are six plates on the muzzle, two of which are perforated for the openings of the nostrils, and form black spots; on the upper part of the head there are two divergent black lines in the form of the letter V; the upper jaw is whitish, with small spots of black, and the under jaw is yellowish; the eyes, which are surrounded by black borders, are very small, but very clear and brilliant; the tongue is soft, very extensible and retractile, divided into two points at its extremity, and of a blackish or greyish colour. The old story of vipers being capable of poisoning with the tongue, and all the metaphorical allusions to the poisonous tongues of serpents which are founded upon it, must be placed in the category of idle stories.

The varieties of the common viper may be ranged according as one or another of the tints which enter into the general colour is the more predominant. They are accordingly red, brown, grey, blue, and black, but still these are only shades of difference, the causes of which are not known, and which occur at the same places, and even in the same family; the brown and grey, as being the intermediate tints, are the most common.

When let alone, vipers are very quiet and inoffensive animals, never in the least interfering with man or his operations, but is rather serviceable to him, by eating insects, worms, mollusca, field-mice and moles. They are active only for a portion of the year, always the shorter the more northerly the climate; and when they hibernate, a number of them are often rolled up in a bundle in the same retreat.

The females are ovoviviparous. The eggs vary from a dozen to about two dozen in number; the gestation lasts about eight months; the eggs, when matured, are about the size of those of the wren; and when the young at first burst the membrane, and come out of the oviduct of the parent, they remain some time "on the egg," as is the case with the young of the ovoviviparous fishes; but they do not, according to the vulgar statement, take refuge in the body of the mother after they have been produced. This species, and not any of the non-venomous snakes, is the *Adder* of common language, the *Neidr* of the Welsh, and the *Nathair* of the Scotch Highlanders; though the common snake often gets the name and comes in for a share of the persecution, and of all the superstitious beliefs connected with the adder. It is eagerly eaten by the wild boar, and also by various species of birds; these, however, take the precaution of bumping it on the head, or beating its head against the ground, until it is incapable of using its fangs.

It is doubtful whether the *æspirig* of Scandinavia, and some other places of the north and the east of Europe, is any thing else than the common viper.

Horned-muzzle Viper (*V. ammodytis*), is not uncommon in the valley of the Danube, and in countries further to the south. It has a soft bone covered with small scales in advance of the muzzle; but, in other respects, it differs but little from *Lucus*, though in proportion as it is a more southerly inhabitant, its venom may be presumed to be more active.

Horned Viper (*V. cerastus*). This one has a small projecting horn over each eye; it is of a greyish colour, inhabits the hot and dry parts of Africa, especially the borders of the valley of the Nile, and conceals itself in the sand.

The tufted Viper (*V. lophophris*), is an analogous species found in Southern Africa, but instead of the two projecting bones over the eyes it has two tufts of filaments.

The short-tailed Viper (*V. brachyura*), is a foreign species, with the scales on the head keeled and imbricated like those on the back; it inhabits warm regions, and is represented as being very poisonous.

The brown and white Viper (*V. hæmachates*), is a South African species, of a reddish-brown colour marbled with white; it has plates on the head very similar to those on the colubers, and the lower part of the muzzle is bevelled off.

NAIA. These are, generally speaking, of small size, but they are remarkable for the virulence of their poison. They are found in very warm countries, such as India and Egypt, and lurk about ruins and among stones and rubbish. They have plates on the head, and they have the power of inflating the body immediately in the rear of the head by advancing and expanding the anterior ribs.

Nais tripudians is the most notorious species. It abounds in the warmer parts of India, where it is called *cabro capello*, hooded snake, by the Portuguese; and it is also called the *spectacled serpent*, from a black mark, something in the form of a pair of spectacles, which appears on its inflated disc. There are one or two coloured varieties, as in the common viper, but they are all equally poisonous. They are animals of some speculation; for the Indian jugglers teach them to dance and play a number of tricks, pretending to charm them; but the safest part of the charming is the extraction of the poisonous fangs.

Nais Haje. This is an Egyptian species, which has been celebrated from the remotest antiquity. The inflated neck, and often the erect attitude, which we observe in the serpent of the ancient paintings and sculptures of Egypt, is proof that this is the serpent which they made the emblem of the protecting divinity of the world, and, as such, placed it as a guard, at each side of the globe, upon the portals of all their temples. There is little doubt that, if Cleopatra did poison herself by the bite of a serpent, the haje was the *aspic* which she employed for the purpose—only it could not have been procured from the mud of the Nile, as it is not aquatic. Its markings are greenish and brown, not yellowish and bluish-brown, as in the preceding; and it cannot inflate the anterior part of the body to such a degree. It has been taken advantage of by the jugglers as well as its congener, who, by pressing its occiput, can make it as stiff as a stick, so as alternately to seem a rod and a serpent. The power that it has of erecting itself when alarmed, or otherwise excited, is probably the reason why the office of a guardian was conferred upon it.

ELAPS. These have the head furnished with plates; but the bones of the anterior part of the body are very different from those of *Nais*; for, instead of the ribs being dilatable, the jaws can hardly be separated from each other in consequence of the shortness of the tympanal bones; their head, in consequence, seems one continuation with the body. They form an exception to the general geography of the vipers, in being found in the tropical parts of the American continent as well as in the East. Perhaps they ought to be formed into a distinct section. They are the *labarra* or *ibarra* snakes of Guiana, and neither so large nor so formidable as the *crotales* of that part of the world. The one best known is *E. lemniscatus*, of which the ground colour is white, marked with rings of black, approaching each other in species, and one of the black rays forming the point of the muzzle. The poison of this one is much dreaded; and, as is the case with the viper of Britain, it brings part of its bad name upon some of the harmless serpents, which have the misfortune of bearing some resemblance to it in their general appearance.

There are many species of *Elaps* in different parts of the warm latitudes which resemble each other in the marking of their colours, and some of them, from the stoutness of the tail, have been called *Micruri*.

PLATURI have plates on the head, and a double row on the tail, with the tail flattened for swimming. They are found in the Indian seas.

TRIMERSURI have some of the plates on the tail single and others double.

OPLOCEPHALI have very large plates on the head, and all those on the tail single.

ACANTHAPLEIS will be found noticed in its place in the alphabet.

ECHIS, or **SCYTALI**, have the scales on the head small, and large single plates on the under side of the tail.

LANGAGA are but little known. They are said to be of Madagascar, to have plates on the head, the muzzle narrow and projecting, the anterior part of the tail furnished with rays which invest it all round, and the terminal part with small imbricated scales on the under side as well as the upper.

BUNGARI, called also **Pseudonoca**, or false boa, have large entire plates on the under side of the tail,

like the boa, *crotalus*, and *echis*. They have the head short, and covered with large plates, and the occiput broad; they have also a keel of enlarged longitudinal scales along the back. Their most remarkable character, however, is the compound structure of the mouth, which has the maxillary teeth of the swallowing serpents and the fangs of the poisonous ones in the same row upon the same bones. These fangs are of course not worked in the same way as those which have the poison fangs apart. Serpents of this description are natives of the East, where they are sometimes called rock serpents. Some of them grow to the length of six or seven feet.

VIRGIN'S BOWER, is the *Clematis flammula* of Linnæus, a common ornamental climbing shrub in gardens.

VISCUM (Linnæus). The *V. album*, the white mistletoe, is one of the most remarkable English vegetable productions, and often noticed in the Druidical history of the country. It is a perfect parasite, fixing itself on the stem or branches of other trees, and subsisting on their sap. The unisexual flowers are on different plants, and where these are accidentally intermixed, the female plants bear abundance of white viscid berries, forming the principal winter food of the mistle thrush. When a mistletoe is found on an oak, the whole tree was formerly considered sacred by the superstitious votaries of other days, and solemn rites were performed in the shade of the tree. The seed, stuck upon the smooth bark of any tree suitable to its growth, strike root readily. The whitethorn, crab apple, lime, and several others, are frequently seen garnished with mistletoe. The plant belongs to the small order *Loranthæ*, which receives its title from the *Loranthæ* of the tropics, a plant of similar character with the *Viscums*.

VOLUCELLA (Geoffroy). A genus of large dipterous insects, belonging to the family *Syrphidæ*, having the body short, robust, often hairy, and much resembling humble-bees; the antennal seta is plumose, the third joint oblong; the larvæ of several of the species reside in the nests of *Bombi* (humble bees), being parasites; and hence it is that we find them clothed in a garb very much resembling the insects upon which they are parasitic, so as, in fact, to deceive their fosterers, and permit them to enter their nests unmolested. The type is the *Musca inanis* of Linnæus. There are four other British species.

VOMIT NUT is the fruit of the *Strychnos nux-vomica*, a plant having pentandrous flowers, and belonging to the natural order *Apocynææ*, a native of the East Indies. In our collections it is a stove plant, and propagated without difficulty.

VULTURE (*Vultur*). A genus, or more correctly, *Vulturidæ*, a family, of diurnal birds of prey, differing from the *Falconidæ*, or hawks, eagles, &c., in being not so much regulators of the numbers of living birds and small quadrupeds, as cleansers of the earth from the dead bodies of such as have perished by other means. They are the winged scavengers of the land, *par excellence*, just as the storks are the scavengers of the inland waters, the gulls on the shores of the sea, and the petrels upon the broad waters.

They are in some measure geographically reversed upon the other grand division of the *Accipitres*. The head-quarters of that division are in the north; and though they are not absolutely wanting in any one latitude, the species in the tropical countries are com-

paratively few and feeble; and those of the higher latitudes of the south are not very many in comparison with what are found in the north.

The vultures, on the other hand, have their head-quarters under the equator; they are, latitude for latitude, more numerous in the southern hemisphere than in the northern; and in the very high latitudes of the latter there are none. It must not here be inferred, however, that the vultures are birds of delicate constitution, capable of living only in the warm regions of the world. They are the very reverse of this; their office in nature is a rough one, and they are organised and tempered for "roughing it" through life. In their highest latitudes they are birds of the cold and wild mountains, neighbours to the perennial snow; and they very rarely descend to the plains, and when they do it is only as stragglers, or rather as strays, wholly out of their proper place.

Regions, where the weather is in extremes, not the extremes of summer heat and winter cold, as we find them in the polar countries, but the shorter and more violent changes of the weather, and the conflicts of rain and drought, occasion that kind of devastation which finds food for the vultures, and calls them in to clear the surface of corrupting matter which cannot be removed by animals of any other kind. Hyænas and jackalls may do the work very well in the plains, or in those tropical woods where the violence of the changes of weather causes a frequent destruction of animal life; but no animal having only feet as organs of motion could travel over the Alps or the Andes, or any other lofty ridge of mountains, where the food that is for them might be encircled by precipices thousands of feet in height. Nor is it much better in some of the more tangled forests, where the openings in which the dead bodies of animals are most likely to be found, are parted from each other by trees of mountain height, and fairly barricaded against the passage of an animal on foot, except at so slow a rate, as that it would inevitably perish in toiling from the place of one meal to that of another. The food is there, and the general principle of "no waste," which is so easily traceable through the whole of Nature, demands that as there is food there should also be feeders regulated to its quantity, and adapted for reaching it with the least possible exertion. Did our limits admit, we could very easily show that the vultures are the very animals who can perform this duty in Nature in the very best manner. They are birds of immense wing in proportion to the weight of their bodies; their flesh is tough and rigid; their plumage is so little liable to be injured by the weather, that nothing appears to agree better with them than thorough soakings and alternate exposures to wet and dry, as even in confinement they frequently wash themselves thoroughly, and hang out their wings to the sun and air to be dried. They can also endure hunger for very long periods of time; and when they do meet with a prize in the way of food, they can gorge to an extent equal to that of the great crushing serpents; in fact, till they lie benumbed on the ground for a considerable time. But these surfeits, as they would not fail to be in the case of an animal that fed frequent and moderately, do not appear to injure the species which naturally practise them. The time of inactivity after the full meal appears to be a time of great renovation of the system; and the matter thus obtained appears to be capable of performing the functions of life for a long time without a fresh renewal.

The general characters of the vultures are: the eyes flush with the head, and not enfolded under a brow, or standing prominent to command a horizon; the tarsi are not covered by protecting plates, but reticulated, covered with small scales let into a sort of network, as they generally are in the wading birds; the beak is long, nearly straight in the greater part of the length of its cutting edges, and hooked only in a portion toward the tip; a greater or smaller portion of the head, and even of the neck, is bare of feathers, and if not absolutely naked skin, covered only with thin short and soft down; the power of their talons is by no means in proportion to the size of the birds, and they are not much used as weapons; the bill is the member upon which they chiefly depend, and it has more the character of a cutting than of a killing instrument; their wings are so very long, that they are obliged to carry them partially expanded when they walk; they are loosely made and cowardly birds, and feed chiefly upon carrion, and rarely upon living prey. After they have gorged themselves with food, their craw forms a large protuberance beneath the furcal bone, a flow of fetid humour distils from the nostrils, and they are often in such a state of stupidity and inaction, that they are incapable of escape or defence, and one may catch them or knock them down with a stick. Their office in Nature is a foul one, and when they have performed it, they are foul and offensive birds—but not upon that account the less in character.

Cuvier divides them into four sections, which gradually approach a little more to the *Falconidae*, though the best formed of the vultures are very inferior to the worst-formed of that grand division of the *Accipitres*. These sections are *Vultur*, *Cathartus*, *Percepropterus*, and *Gypætus*.

VULTUR. Has the beak thick and strong, with the nostrils placed transversely at its base; the head and neck without feathers, and the skin smooth, without caruncles or warty protuberances. They have also the neck surrounded by a collar of produced feathers or down on the lower part, between the naked portion and that which is covered by the regular plumage of the body. Those which have three climates are found in the eastern continent only; and the difference in the American ones which range in this section or subgenus will be noticed. The species have been much confounded by authors, and many ridiculous stories have been told concerning them.

The Tawny Vulture (V. fulvus), is a large bird, and has been long known to natural history. It is pretty generally distributed over the warmer parts of the eastern continent, occurring in the mountains. The general colour of the mature bird before it is affected by old age, is grey or brown, and fawn on the upper part; the down on the head and neck ash-colour; the collar white, or white mixed with brown; the quills and tail-feathers brown; the bill and feet lead-colour; and the belly in general white. The total length of the bird is about three feet and a half, and the extent of the wings not less than eight feet. The down on the head is very short, but it forms a sort of tuft on the occiput; the skin of the upper part of the breast over the craw is furnished with a tuft of hair, and when the craw is empty it falls in and forms a pit; but after a full meal it swells out and becomes a protuberance. It is subject to considerable varieties of colour at different ages; and additional diversities have been

produced by confounding it with others. Buffon, for instance, has given the figure of it along with the description of another species.

In summer it appears in numbers on the Alps, the Pyrenees, and other mountains of the south of Europe, but it retires into Africa in the winter, over which continent it is pretty generally distributed; but it is everywhere of a roving disposition. It is not a very handsome bird under any circumstances; and when it is in a state of repose, it retracts the neck between the bones of the shoulders, and nearly conceals the head in the feathers.

The Brown Vulture (V. cinereus) is a more daring bird, and often larger in size than the preceding. It is more apt to attack live animals, especially such as are wounded, or in a weakly condition. It is blackish brown on the upper part, with the collar of long and bristling feathers advancing obliquely toward the nape, where there is a tuft of feathers. The feet and the naked skin at the base of the bill are bluish violet. The feathers on the tibiae are long, and hang down considerably beyond the tarsal joints; but the tarsi themselves are not feathered, as alleged by some. Its colour changes much with age, and it is generally distributed over the wilds of the south, and also dis-cursive.

The Eared Vulture (V. auricularis) is an African species of a blackish colour, with a fleshy crest on each side of the head under the openings of the ears. There is no down on the head and neck of this species; the naked skin on these is reddish and violet, that on the front of the neck black; the under part of the body is brown; the bill yellow at the base, and horn-colour toward the tip. It is a large bird, and remarkable for the stretch of its wings, which are said to be at least three times the length of the body, and that, in the full-grown bird, is not less than three feet. It is abundant in the wild and elevated districts of Southern Africa. Some of the vultures of India have a considerable resemblance to this one, only the fleshy appendages to the sides of the head and the upper part of the neck are not so prominent. It is by no means improbable that there are many varieties differing a little from these in the wild parts of central Africa and of Southern Asia.

The American vultures which have the nearest resemblance to those now described have the membrane, at the base of the bill, covered with fleshy tubercles; and in some of the species the naked parts are very fine in their tints of colour, and exhibit a brilliant play of prismatic colours; but these go off when the birds are dead.

The King of the Vultures (V. papa). This bird is about the size of a goose; and remarkable for its changes of colour, both at different ages and in different individuals, so that it is not easy to form any one description so as to apply to it. In its first plumage it is blackish, then it becomes variegated with yellow, next the feathers on the body are fawn colour, and the quills and collar black. The naked parts of the head are of various brilliant colours, the predominating ones being coral red and yellowish with purple; but they vary so much that they cannot be accurately described. The caruncles are toothed something like the comb of a cock. This is a bird of the low grounds rather than of the naked mountains, and it is said to nestle in holes of trees, and to have two eggs in a hatch.

The Condor (V. condor) is the celebrated vulture

of America, of whose size, strength, and daring, so many marvellous tales have been told, that had there been any such animals as elephants in South America, it is highly probable that we should have had an account, "by eye-witnesses," of the condor flying clear over Chimberazo with an elephant in its claws. We have no room to go into its history, and it is not necessary, as it may be found any where, since Humboldt brought it within reason and reasonable dimensions. It is only a little larger than the mountain vulture of the Alps, and its habits are nearly the same; but the appendages to the naked part of the bird bring it more within the present section. The colour is blackish, with great part of the wings ash, and the collar on the neck silky and white. The male has one large carunculated membrane above the bill, and another below; but these are wanting in the female. The female is nearly of a uniform greyish brown; and the young in their first plumage are ash brown, and without the collar of feathers upon the neck. Even after all the exaggerations are discounted, the condor is a bird of no small interest. It is the most lofty-dwelling bird of the whole class; and the regions of storm and earthquake which it inhabits are of themselves well calculated to give it a very peculiar importance.

CATHARTUS are the vultures of North America, some of which have occasionally been confounded with the condor; and, though none of them are equal to that bird in story, they rival, if not exceed it, in size and in power. We cannot go into the details of all the species, of which there are several; and therefore we shall give a few particulars of one as a specimen.

Californian Vulture (C. vulturinus). This is a very large bird, about four feet and a half in length, and nearly ten feet in the stretch of the wings. It inhabits North America to the westward of the Stony Mountains, and is particularly abundant in the lower valley of the Columbia. It is a woodland bird, and does not appear to inhabit very high latitudes, though, like the vultures of the eastern hemisphere, it is more northerly in the summer than in the winter. Their general colour is brown, without any very decided markings; they nestle in the thick woods, choosing the tallest pines in the wildest and most inaccessible parts of the mountain valleys. The nest is composed of sticks and coarse grass, and the pair occupy it for many years in succession. The eggs are two, of a jet black colour, nearly round, and about the size of those of a goose. The hatching time is about the first of June, and the incubation lasts about thirty days. The young are at first covered with whitish down, and five or six weeks elapse before they are able to quit the nest.

Where these birds inhabit is truly a vulture's country, as the turns of the seasons are particularly violent both on land and at sea. Many land animals are beaten down by the rains, or overtaken by the swelling rivers; and when the storm abates, the wreck both of the land and the water is great. This is indiscriminately eaten by the vultures, which make common prize both of fishes and of land animals, and heed not much how far they may be gone in putrefaction. Their senses are keen, especially their sense of sight, and we shall not enter upon the disputed keenness of the sense of smell in vultures, which, to say the best, appears to have been most gratuitously exaggerated. When on the reconnoitre, or tracking

the progress of a wounded animal, they fly very high; and, though there may not be one in sight when it falls, the carcase of a large animal speedily attracts a number of vultures; and they come to a recent carcase just as readily as to a tainted one, to that which does not smell with the same readiness as to that which does, and this is against the common notion of the acuteness of their scent. Indeed the fœtid distillation from their own nostrils is a pretty strong argument against their smelling power; a man with his nose constantly bathed in assafœtida would not be in the best condition for finding roses by the scent. "Their voracity," says the lamented David Douglas, "is almost insatiable, and they are extremely ungenuous, suffering no other animal to approach them while feeding. After eating they become so sluggish and indolent as to remain in the same place, until urged by hunger to go in quest of another repast. At such times they perch on decayed trees, with their heads so much retracted as to be with difficulty observed through the long, loose, lanceolate feathers of the collar; the wings at the same time hang down over the feet. This position they invariably preserve in dewy mornings, or after rains. Except after eating, or while guarding their nest, they are so excessively wary that the hunter can scarcely ever approach sufficiently near for even buck-shot to take effect on them, the fulness of the plumage affording them a double chance of escaping uninjured. Their flight is slow, steady, and particularly graceful, gliding along with scarcely any apparent motion of the wings, the tips of which are curved upward in flying. They are seen in greatest numbers, and soar highest, before hurricanes and thunder-storms. Their quills are used by the hunters as tubes for tobacco-pipes."

The Turkey Vulture (C. aura) is another American species of smaller size, and more generally distributed. It is about two feet and a half in length, and six feet in the expanse of the wings. The upper parts are nearly black, with some white markings, and the lower parts sooty brown. They are common in the United States, but leave the northern ones in the winter.

The Black Vulture (C. atratus) is a darker and smaller species; and so familiar that it frequents the towns, and plies as a scavenger in the streets, in which office it is protected by the inhabitants. It is about two feet two inches in length, and four feet four inches in the stretch of the wings. The general colour is dull black, with some white on the insides of the primary quills. It is a dull and sluggish bird, and the smell of it is peculiarly offensive.

PERCNOPTERUS—Black wings. These have the beak long, slender, a little bulged out of the middle of the lower mandible; the nostrils oval, longitudinal; the head only, and no part of the neck, bare of feathers. These are birds of moderate size, not nearly equalling the vultures properly so called; but still they very greedily devour carrion and all sorts of garbage, and rather than want they gorge the most foul and offensive substances. They are found in both continents.

Egyptian Vulture (P. leucocephalus). This is also, from its abundance in Egypt, called "Pharaoh's chicken." It is about the size of a raven. The cheeks and throat are naked; the general plumage of the male bird white, with the quills black. The female and the young are brown. This species ranges pretty discursively over the eastern continent; and it is the

only species of vulture which is recorded as having occurred in Britain, even as a rare straggler. They follow the caravans in the deserts in large flocks, in order to feed upon the camels and other animals which perish on those hazardous marches, which are fatal to the lives of so many, not only from the heat and drought, which one could readily understand, but from the piercing cold of the night which, at some seasons, follows a burning hot day. The ancient Egyptians paid divine honours to these birds, and we find them often represented in their sculptures and paintings; and, though the Mussulmans of the present day do not actually worship them, they treat them with much respect, as very important birds in a country where cleanliness is so essential, but so much neglected. It is probable that in so wide and varied a country as these vultures are scattered over, there are many varieties, some of which have been named and described as species.

Urubu Vulture (P. jota). This is an American species, common in the warm and temperate parts of that continent, and often confounded with the black vulture, though it is a much smaller and quite a different bird. Its habits are similar to those of the Egyptian vulture; and it renders similar services to the people. It is also about the same size, but the beak is shorter, and the plumage entirely bright black. It is this one, and not the *Atratus*, which is called the "carrion crow" in the United States. Its smaller size, more slender beak, and blacker colour, readily distinguish it from the other. There seem to be some smaller species, or at all events varieties, of this one in America.

GYPÆTOS—Griffons. These are the most bold and powerful of all the vultures, and approach the *Falconide*, with which they have been associated by some describers; but still they are vultures in their essential characters. They have the eyes level with the head, and the talons feeble; their wings are half spread in repose, and their craw sticks out when full, as in the more typical vultures; but their head is entirely covered with feathers, and in the following respects they make an approach to the eagles: the bill is very strong, straight in the greater part of its length, and much hooked at the tip of the upper mandible, where it is enlarged; the nostrils are covered by rough hairs, and there are tufts of hair projecting obliquely at the gape; their tarsi are short and feathered to the toes; their wings are long, and the third quill the longest. These characters show that they have more hardship to endure than the other vultures.

The Læmmer-geyer or Lamb Vulture (G. barbatus) is the typical bird. This is a sturdy mountaineer, inhabiting, but not abundantly, the summits of the most wild and elevated ridges, and nestling in the inaccessible cliffs in a manner similar to the eagles. It has been perhaps more exaggerated than any other bird, except perhaps the condor. It is in all probability the *roc* of the Arabian tale; and some describers have assigned it an extent of eighteen feet in the wings, which appears to be about double the real quantity; and the length is about four feet, the tail being long and strong. The upper plumage is black, with a white line on the middle of each feather; the neck and all the under part of the body a clear fawn colour; a black band across the head; and the band or tuft of hair, which projects from the gape, black. It stands accused of carrying off lambs, goats, cha-

mois, and even the hunters, when they are benighted and sleep on the mountains. It is also accused of hovering over the villages and carrying off children. It is further said to drive animals over the precipices, in order to feast on their mangled remains;—all of which must be taken *cum grano salis*. Still it is a formidable bird, as well on the mountains of Africa and Asia as on those of Europe.

WAGTAIL (*Motacilla*). A genus of dentirostral bird, belonging to the fine-billed section, and having some characters in common with the warblers, the greater part of which were in the older arrangements included in this genus. See BIRD, CURRUCA, SYLVIA. It has been reduced to comparatively few species.

The generic characters of the wagtails are: the bill still more slender than that of the warblers; the tail very long, and in continual motion upward and downward; the tarsi long; and the scapular-feathers so long as to hang over the turn of the wings, as in the stilt-birds, which run by the margins of the waters. In fact, the more characteristic wagtails are aquatic birds in their habits; and though they capture great part of their insect prey on the wing, they also capture a good deal while they are running, or in the shallow waters, where they perch upon stones, waiting what may come. As they are exclusively insectivorous, they do not remain during the winter in the colder latitudes, or in places where the water is apt to be frozen. Limited as the genus is in the modern system, it is, in Cuvier's arrangement, divided into two subgenera, *Motacilla*, wagtails properly so called; and *Budytes* (shepherdess).

MOTACILLA. These have the hind claw short and crooked, as in the rest of the fine-billed section; and they are found only near waters. There are two British species.

Pied Wagtail (M. alba). This species is very much distributed over the country in the summer, always near the pools and streams, to enjoy which it advances to a very considerable height up the mountains; and, though it disappears from those places as the cold weather sets in, and food for it is not to be had, it is probable that many remain during the winter. They are handsome birds, and their action in the summer is very amusing. They follow their prey in the air by leaps and jerks, accompanying them by the motion of the tail; and they leap from the ground and catch prey in the same manner. They are very familiar birds, resorting to the close vicinity of houses, and carrying on their labours about the horse-pond quite undisturbed by the cattle or the servants. They also attend the ploughs in the spring, and take their part in clearing the fields of noxious insects; and from their familiarity and their strut, one would be half tempted to believe that the little lively fellows are aware that they are performing a service. At all events, they are in their element; for the plough turns up numbers of larvae, and also of insects, which have been hibernating in the earth. The male sings early in the season, and sweetly, though his song is neither loud nor of much compass or variety; but it sings from a low perch, at a time and in places where we do not expect to hear a song, and this adds to the effect which it produces. The nest is constructed in a hole of the bank under a stone, or in a hole of the wall, and sometimes in thick foliage near the ground. It is constructed with vegetable fibres, feathers, and wool, and lined with hair. The eggs are very small, four or

five in number, of a greyish-white colour, with light bright brown speckles; and the bird is said to have often the ungracious task of raising a young cuckoo at the expense of its own brood, though, in very many of the places where the wagtail breeds, the cuckoo could not possibly get the egg into the nest unless they sent it in a letter. The weight of this bird is about three quarters of an ounce; and the length, of which the tail forms a considerable part, seven inches and a half; the front cheeks and sides of the neck are white; the nape, the hind neck, the chin, and the throat black; the back bluish-black, more or less tinged with ash-colour; two or three of the quills next the body black; and the rest dusky, with broad white margins on the outer webs; the coverts black, the lesser tinged like the beak, and the greater with white tips; the tail-feathers black, with the exception of the distal parts of two lateral ones on each side, which are white. The female is dusky where the other has black, and much more tinged with ash-colour; in winter the black on the anterior part fades off, and is replaced by white, with the exception of a crescent on the breast. In winter many of them resort to the lower estuaries and marshes flooded at high-water, remaining in the withered herbage when the tide is full, and ranging the ground as it ebbs away.

Grey Wagtail (M. bairdii). This species is not quite so common as the pied one, and its colours are not nearly so conspicuous. It is also more migratory. In summer the male has the principal portion of the upper part grey, and the rump and tail-coverts yellow; two white lines diverge from the gape, one over and the other under the eye, and one across the eye, joining them above and below; the throat under the white lines is black, and running with a curve downwards to the breast; the whole of the under part is yellow, bright where it joins the black on the breast, but fading as it recedes upon the belly; the wings are greyish-black, with white tips to the coverts; the tail is black, with some white on two or three of the lateral feathers; the bill and also the inside of the gape are black; and the feet are brown, marked with a yellowish garter on the tarsal joint. The female has the yellow paler, and the grey with a blackish or tarnished shade; but the male fades to the same tints in the winter. Besides being less abundant than the pied wagtails, these birds are more retiring in their habits; and thus they are much less frequently seen. They collect in the southern parts of Britain in the winter, and are then known only, or chiefly, as winter wagtails; and they quit these places in February or in March, according to the season, and spread themselves over the heights, without, however, reaching so far to the north as the other species. They breed by the streams in the upland moors of the south, but not in the low and rich places to which they resort in the winter. The nest is usually placed in the rocky banks, and seldom in a cover of vegetation. The nest is much the same as that of the pied one; but the eggs are large, of a yellowish colour, and brighter in the spots. In their more southerly haunts they have often one brood early in June, and another about the middle of July; but in less genial places they have only one about midsummer. Their food at all seasons consists chiefly of water insects and their larvæ, and very small and soft crustacea and shelled mollusca.

There is more propriety in the separating of these birds from the warblers than appears at first sight.

While they were associated with these in the system, they were also associated with them in manners; whereas they are birds of a quite different habit; birds of the open air, not of the grove, altering their plumage with the seasons more than their place; and having several points of resemblance with the pipits.

Budytes. These birds are also with propriety separated from the wagtails, on account both of their structure and their haunts and habits, and their general form and action, but the claw on their hind toe is nearly straight, and lengthened as in those pipits which most nearly resemble the larks. The structure of the foot is adapted for walking upon grassy surfaces; and, accordingly, the birds are chiefly found upon them. They are insectivorous as well as the others; but they seek for insects in the fields and meadows, and follow the flocks and herds, about which there are usually numbers of insects. It is for this reason that they are called little shepherds or shepherdesses by the French, which is also the meaning of their Greek generic name *Budytes*. There is only one European species.

The Yellow Shepherdess (B. flava). While this bird stand in the list of the wagtails, the epithet yellow was by no means a happy one, inasmuch as there is less yellow upon it than upon the grey wagtail. The green wagtail would have been more appropriate if the generic wagtail had been retained; but as there is a difference of habit along with the difference of colour, the bird is much better in a separate genus.

It is a much rarer bird, at least much more local in its distribution, than any of the wagtails; and it is more of a migrant, and probably leaves Britain entirely in the winter. It appears in March, rears its brood about midsummer, and migrates in September, although a few appear to remain in the marine pastures near the Channel. It is but seen on its coming in the spring; and thus it has been called the "oat-seed bird" in England, and the "spring wagtail" in France. The male is olive-green above in the summer, darker on the back; the wings and tail are dusky with but little white, and the under part is yellow, bright anteriorly, and very pale backwards; The female is almost white on the under part; the nest is in a tuft or under a bush upon the ground, and never in holes of banks, or under stones; neither is the bird found hawking for insects over the water, or running on the sludgy shores, as is the case with the wagtails properly so called.

WALRUS. See MORSE.

WAPITI. See DEER.

WARBLER. See CURRUCU and SYLVIA.

WASP. The name of a well-known hymenopterous insect, belonging to the section *Aculeata*, subsection *Diploptera*, family *Vespidae*, and genus *Vespa*. In the articles DIPLOPTERA and ODYNERUS we have already noticed the distribution of these insects and the habits of the solitary species of wasps. We shall therefore here confine our remarks to the social species, which constitute the genera *POILSTES* (which see), and *Vespa*, which, in its present restricted state, comprises only six British social species of the Linnean *Vespa*, the largest of which is the HORNET (which see). The five other species are of smaller size, the common wasp (*Vespa vulgaris* of Linneus) being the type of the genus, which is distinguished by the existence of three kinds of individuals in the community, namely, males, females, and neuters, by

having the upper part of the inner margin of the mandibles as long or longer than the other part; the front of the clypeus is broadly truncate in the middle, with a tooth on each side; the abdomen is always oval or conical. Early in the spring a few large wasps may occasionally be observed flying about, and actively engaged in obtaining materials; these specimens are females which have survived the winter, harbouring in suitable places, without having deposited their eggs, which the returning warmth of the ensuing spring induces them to do; first, however, constructing a nest in some hole in the ground. Here the insect not only forms an outer covering, but constructs a layer of cells of an hexagonal form, in each of which she deposits an egg; the larva is hatched in a few days. Wasp grubs are well-known baits for anglers: they are destitute of legs, and remain within the cell in which they are born, being fed by the parent wasp; as soon as they are full grown the larva closes the mouth of the cell and becomes a pupa. In a week or ten days more this first brood appears in the winged state; but here commence the wonders of the wasp nest; all these first-born specimens are destitute of sexual instinct, being neuters, created only for the purpose of assisting their common parent in enlarging the nest, constructing fresh cells, and feeding their younger brethren, which are still in the larva state, the egg-depositing process still being continued by the old foundress wasp. It is not until the latter part of the summer that the development of the male and female wasps takes place, the latter are not, however, driven from the nest as soon as produced, as in the case of the hive-bees, and consequently there is no swarming of wasps analogous to the swarming of bees; they remain in fact for some time in the interior of the nest, only quitting it at the beginning of the autumn; they now pair, the males soon dying; but scarcely more than a dozen out of the three hundred females, of which the nest is composed, survive the winter, to become the foundresses of fresh colonies in the ensuing year. After this dispersion, the great object of the construction of the nest having been accomplished, the community is at an end, the neuters soon disperse and die, and the nest is rendered a desolate ruin. A full-sized wasp-nest is nearly a foot in diameter, of a globular form, the outer covering composed of numerous layers of a very thin substance like paper, which the wasps construct of comminuted bits of wood: this covering is more than half an inch thick. There are several (eight in a large nest before the writer at the present time) layers of cells: each of these layers is about two-thirds of an inch deep, separated from the next upper and under layers by a space of about half an inch, the layers being supported by numerous strong pillars. There are about 16,000 cells in a nest, differing in size according to the three orders of individuals composing the community; it is generally in holes in banks, &c. that the wasps construct their nests. Wasps are very ferocious creatures when disturbed, and their stings are to be dreaded. They feed upon sweets of various kinds as well as upon flesh, and other insects; they seize the common house flies with avidity, and are very fond of honey. The nests of the other British species are not to be compared in point of size with that described above. *Vespa media* of Latreille, and *Britannica*, Leach, which are probably identical, make their nests on trees, attaching them at the extremity of the branch, where they

resemble, in size and colour, a Welsh wig hung out to dry. According to the author of the *Insect Architecture* they are more common in the northern parts of the country, being seldom met with in the south; the tree which this species prefers is the silver fir, whose broad flat branch serves as a protection to the suspended nest, both from the sun and the rain. The materials of the construction are nearly the same as those of the common wasp.

Vespa holsatica constructs its nest of a singular form; it is nearly globular, and enclosed beneath in a saucer-like covering, and is placed in the interior of granaries, or attached to the beams of unfrequented apartments. Another species attaches its nest to various low shrubs. We have been favoured with the two following sketches of a nest of this kind, of small size, found in Oxfordshire, and which consisted of about a dozen cells only. It is somewhat like the

nest figured by Rösel, which Kirby and Spence gave as that of *Vespa parietum*; but that species is solitary, and belongs to the genus *Odynerus*.

Another nest is described by Reaumur, of a depressed globular figure, composed of numerous envelopes, so as to assume a considerable resemblance to a half-expanded Provence rose. In Reaumur's specimen there were two layers of cells, and a large open space in the centre, which would most probably, in due time, have been occupied by other layers of cells.

WEEVIL. The ordinary name given to various species of coleopterous insects belonging to the family *Curculionidae*, or the Linnæan genus *Curculio*, and more especially applied to the different species of the genus *Calandra*. See *CURCULIONIDÆ* and *CALANDRA*.

WHIRLWIG. The common English name of the *Gyrinus natator*. See *GYRINIDÆ*.

WHITE ANT. See *TERMITIDÆ*.

WILLOUGHBEIA (Scopoli). An East Indian tree, having pentandrous flowers, and belonging to the natural order *Apocynææ*. This plant yields caoutchouc, which is extracted from it in the East, where the trees grow naturally. The plant is easily kept and propagated in the stove.

WIREWORM. This name is applied to the cylindric wire-like horny larvæ of the species of insects belonging to the coleopterous family *ELATERIDÆ* (which see), some of which are very destructive to young wheat and various vegetables.

WISTARIA (Nuttal). A highly ornamental genus of plants, chiefly natives of China, belonging to *Leguminosææ*. This beautiful genus has borne different names, namely, *Glycine*, *Apos*, *Dolichus*, &c. They may be increased by layers or cuttings, and are the most suitable of all other climbing plants for covering arbours, naked walls, &c.

XANTHOXYLUM (Linnæus). A genus of

shrubs and trees found in the East and West Indies, as well as in North America. The latter do well in the common garden soil, and are increased by cuttings, or by pieces of the roots. They are known as the toothache tree, and belong to *Rutaceæ*.

XEROPHYLLUM (Michaux). A genus of North American herbaceous perennials bearing hexandrous flowers, and ranking among the *Melanthaceæ*. The genus was called *Helonicus* by Nuttall. As ornamental plants they deserve notice, and require a peaty soil, where they ripen seeds, by which they may be increased.

XIPHYDRIA (Latreille; *UROCERUS*, Jurine; *HYBONOTUS*, Klug). A genus of hymenopterous insects, placed by Latreille in the family *Tenthredinidæ*, and formed by Dr. Leach into a distinct family, *Xiphydriidæ*, but belonging to that of *Siricidæ*, having the body cylindrical, the antennæ inserted close to the mouth, slender at the tips; the ovipositor exerted. These are insects of moderate size, which live in the larva state in the stumps of trees, seeming to prefer those of willow grounds. The type is the *X. dromedarius* (*Sirex* of Linnæus), so named from the elongated neck. The other reputed British species is *S. camelus*.

XYELA (Latreille). A genus of minute but very remarkable hymenopterous insects, arranged by Latreille, but improperly, amongst the sawflies (*Tenthredinidæ*), but having the ovipositor nearly as long as the abdomen, and naked; the antennæ are elbowed, the third joint being very long; the maxillary palpi are also very long, and the wings large. Two species are only yet described, but the writer has seen several others, and possesses both sexes of a very large new species, presented to him by Dr. Klug of Berlin, with the manuscript name of *Xyela Dahlii*. Very excellent figures of the genus are given by Mr. Curtis in his British Entomology. Latreille states that the larvæ reside in the interior of vegetables, or in old wood. Brebisson named the genus *Pinicola*, in consequence of the species being found in the neighbourhood of fir plantations. There is only one British species, *X. pusilla*.

XYLOCOPA (Latreille). A very numerous genus of large exotic hymenopterous insects, belonging to the family of the bees, having the body and legs very hairy, the mandibles in the females spoon-shaped, obtuse, and guttered, with two teeth at the tips; the upper lip is horny, and ciliated above; the antennæ are very much elbowed and filiform; the fore wings have three complete sub-marginal cells, the first of which is divided by a small transparent line; the third is the largest, receiving two recurrent nerves. These bees resemble large humble-bees, and have been called carpenter bees, from their habit of constructing their nests in posts and other wooden erections. The body is generally of a black colour, often partially covered with pale-coloured hairs; the wings often stained with violet, copper, or green, and very shining. The male, in many of the species, differs considerably from the female. In a few species the eyes of the male are large and approximating, and the anterior legs are greatly dilated and ciliated. These insects are chiefly inhabitants of tropical countries, to which they give a peculiar entomological character. The type of the genus is the *Xylocopa violacea*, a species which occurs in the central and southern parts of Europe, of a black colour, with fine violet wings, the female of which

constructs her cells in dry upright palings, &c., into which she first bores obliquely for an inch, then changing the direction, she burrows perpendicularly for a foot or more, her burrow being about half an inch in diameter. Having completed this burrow, she commences the construction of her cells, forming them of the gnawed wood which she has collected at a short distance from the nest. Having formed a cell at the bottom of the burrow, and filled it with a supply of pollen paste sufficient for the entire subsistence of one of her progeny (the egg of which she introduces into the pollen), she stops up the mouth of the cell with a lid of sawdust kneaded together, which serves as a floor to the superincumbent cell, proceeding in this manner until the burrow is filled. As she is several weeks in completing these operations, it is evident that the egg deposited in the lowest cell will produce the perfect insect before the rest; and in order to prevent it from disturbing the upper individuals, the parent bee has the instinct to construct a lateral opening at the bottom of the cells, which prevents the egress of the young bees as they successively arrive at perfection. None of the species of this interesting genus are inhabitants of this country.

XYLOPHYLLA (Linnæus). A genus of curious evergreen shrubs, chiefly natives of the West Indies. Their flowers are monœcious, and belong to *Euphorbiaceæ*. These plants are remarkable for bearing their flowers on the edges of the leaves. The species are easily increased by cuttings rooted in sand, under a glass, on moist peat.

YEW TREE. This common and well-known tree has been already noticed under *TEXAS*; and it may be only necessary to add here that, though placed in *Diæcia* by Linnæus, individual trees are found with both male and female flowers upon them.

YPONOMENTIDÆ (Stephens). A family of small lepidopterous insects, belonging to the section *Nocturna*, distinguished by having generally two, rarely four, palpi; the wings entire, the anterior pair mostly long and narrow, with shortish ciliæ; the posterior generally large, folded on the inner edge with long ciliæ; the body slender, elongated, and often depressed, acute in the females, and tufted at the tip in the males. These insects are of small size, but of considerable diversity in their appearance. From the *Tortricidæ* they differ in having the palpi long and slender, and from the *Tineidæ* in having only two palpi. Some of these insects reside in their larva state on flowers, upon which they subsist; others are found within the surfaces of leaves, devouring only the parenchyma; some form extensive webs, and live in society; others are solitary. Among the subcutaneous species are some of the most brilliant of the lepidoptera, their wings being adorned with highly polished scales, and some of them being extremely varied in the number of tints; others, again, are very plain; the former set have generally drooping palpi, the latter ascending recurved ones. The species, and even genera, are very numerous, including the japanned, or long-horned moths (*Adela*, Latreille), which are to be found in the early summer months hovering over bushes in great swarms, and distinguished by the great length of their antennæ; *Yponomenta*, comprising, *Y. evonymella*, *Y. padella*, &c., the larvæ of which reside in webs, and often entirely strip the white thorn hedges of their foliage; the moths being white, with numerous black spots,

whence the names of the little ermine moths, *Anacampsis*, *Argyromiges*, &c.

YUCCA (Linnaeus). A conspicuous genus of herbaceous and half-shrubby ornamental plants, chiefly natives of America. The flowers are hexandrous, and the genus belongs to *Tubifera*. The most tender sorts are kept in the greenhouse or conservatory, and the hardy species do well in the open air. They are all magnificent flowering plants, and increased by suckers.

YUNX—Wryneck. A genus of zygodactylic, or climbing birds, belonging to that portion of the order which run upon the bark of trees, and perch lengthwise upon the branches, and not to those which climb by grasping the twigs, as is done by the parrots and the allied tribes. In Cuvier's arrangement they are placed between the woodpeckers and the cuckoos, but they have most resemblance to the former. The term "wryneck" is given not because the necks of these birds are "a-wry" more than those of any other birds, but because they have a wonderful power of twisting the neck with great facility, and in all directions. It can not only be bent in any plane, but it has so much twisting motion, that the bird can turn the bill and forehead fairly round in the direction of the back; and thus, while the axis of the body remains perfectly still, the bird can, in proportion to the length of its bill, command more space, and command it with more freedom and celerity, than any known bird. This at once leads us to conclude that the bird subsists upon very small food.

The generic characters are: the bill short, straight, in the form of a depressed cone, slender at the tip, rounded on the culmen, and with the cutting-edges entire; the nostrils pierced in the grooves at the sides of the ridge of the culmen, naked of plumage, and in part covered by membrane; the tongue extensile, as in the woodpeckers, and with a horny or hard cartilaginous point, but without any barbs; the two front toes united at their bases, the two hind ones entirely free; the wings of mean length, the second quill the largest. There is only one characteristic species, which was known to the Greeks, who called it *Yunx*, and the Romans called it *Torquilla*.

COMMON WRYNECK (*Yunx torquilla*). This bird appears in the south of England as a summer visitant, and frequents the warm and dry soils—the very opposite ones from the woodpeckers. Its chief food is ants and other little insects, which it collects with wonderful rapidity from the bark of trees, and also from the ground. Sunny days are those upon which it is especially active. It is about the size of a lark, and nearly of the same colours, only they are much richer in the tints and more beautifully mottled. The ground colour of the upper part is yellowish brown, variegated with spots of darker brown, and arrow-head lines of black; and there is a very distinct mesial line of black along the back, and especially on the neck; the under parts are greyish-white, with arrow-head spots of black, forming bars; the quills are brown, with black margins; the tail-feathers mottled brown, also margined with black; the tail-feathers are long, but they have not the stiffness of those of the woodpeckers. The bird does not require this, either in the preparation of its nest or in the finding of its food. It prefers a hole of a tree for its nest; and if it does not find one quite suitable for its purpose, it can make improvement, but it never actually digs a hole. Neither does it dig into the wood for

any part of its subsistence, though it picks it fast enough from the bark. In the spring these birds are partially social; and the bird-catchers to the south of London decoy them into their snares by imitating their call-note, which has some resemblance to the cry of a small hawk, only it is more subdued and feeble. The eggs are as many as nine or ten, and they are hatched on the wood-dust in the hollow tree, without any materials placed as a formal nest. When the wryneck meets with a plentiful supply of ants, and keeps picking them up right and left, the flexures of the mesial line change so rapidly, that it appears to glide onward like a snake.

Cuvier makes the genus *Picumnus* a section of this one. See *PICUMNUS*.

ZABRUS (Clairville). A genus of coleopterous insects, belonging to the family *Carabidae* and subfamily *Harpalides*, having the body very thick and robust; the external maxillary palpi filiform, the last joint being shorter than the preceding, the mandibles shorter than the head, &c. These are insects of moderate size, and generally black colours, which are often found in the neighbourhood of corn-fields, to which, as we learn from a memoir by Germar, the *Zabri* are often very injurious, by feeding upon the young plants in company with one of the *Melolonthidae*. Mr. Stephens considered, however, that it was for the purpose of feeding upon the larvæ of the latter that the insects were found in company together; but Mr. Rudd has clearly proved the contrary in a memoir published in a recent number of the Entomological Magazine. The type of the genus is the *Carabus gibbosus* of Fabricius.

ZAMIA (Linnaeus). A very remarkable genus of rigid herbaceous plants, natives of South Africa and the West Indies. The flowers are dioecious, and belong to the natural order *Cycadeæ*. This genus has somewhat the habit and character of palms, having short thick stems, crowned with a tuft of harsh much-divided fronds, from among which the florescence is produced. The *Z. Caffra* is the bread-tree of the Hottentots, its pith being extracted and manufactured into a kind of flour.

ZEA (Linnaeus). An important genus in those countries suited to its growth. It is an annual belonging to *Gramineæ*, and is the famous maize or Indian corn so much extolled by the late Mr. Cobbett, as suitable for English cultivation. It has been fairly tried in this country, and in many instances with considerable success; but comparing the expense of cultivation, and the risk of the crop being injured by frost, and as food for either man or cattle, it is not to be compared with common wheat for bread, or common beans for feeding cattle; it may be superior for feeding poultry, perhaps, but poultry can scarcely be called a necessary of life to British society.

ZEOLITE, or **MESOTYPE** as it is sometimes called, is a mineral, of which there are several varieties; the acicular zeolite is of a grey or reddish-white colour. It occurs in massive, and in distinct concretions, which are both massive and granular. Its two ordinary forms are exhibited in the next page.

There is a very curious peculiarity in this mineral, which it shares with some others, but which phenomenon it is singularly well fitted to exhibit. If the zeolite be heated it shows very distinct electrical symptoms, and retains this property for some time after it has cooled; thus one extremity of the crystal

exhibits an excess of electricity, whilst the opposite end is in a negative state. Fine specimens are found

in Dunbartonshire, and some other parts of Scotland; it is also brought from America. The other forms of zeolite are more rare, and excite but little interest.

ZEUZERA (Latreille). A genus of moths, belonging to the family *Hepialidae*, and comprising a single British species, *Z. Esculi*, known to collectors under the name of the Wood Leopard, being of a beautiful white colour, with numerous small black spots; the male is distinguished by the antennæ, which are pectinated only half their length, the extremity being simple; the female has the abdomen terminated by a very long and retractile telescopic ovipositor, fitted for introducing her eggs in the crevices of trees. It feeds on the wood of the pear, apple, service, quince, and probably of all the *Rosaceæ*, as it is known to do on the horse-chestnut, lime, walnut, beech, birch, and oak, into which the larva bores, forming burrows half an inch in diameter, and so greatly injuring the timber. This larva is of a deep fleshy yellow colour, with black spots and a black head. It remains two years in this state and about a month in that of the chrysalis, the abdominal segments of which are furnished with reflexed hooks, enabling the chrysalis to push itself to the orifice of its burrow, so as to effect its escape without difficulty on arriving at the perfect state.

ZIMB (*Tralsalyia*). An insect first described by Bruce, the African traveller, but of which no subsequent information has been obtained by travellers in the deserts of Africa; so that, notwithstanding the confirmation of many of Bruce's most marvellous-seeming statements, the account of the zimb is becoming a matter of doubt. We mention it, however, in this place because we perceive that at the last meeting of the Zoological Society Mr. MacLeay called the attention of the members to this subject. "This insect," says Bruce, "is a proof how fallacious it is to judge from appearances. If we consider his small size, his weakness, want of variety or beauty, nothing in the creation is more contemptible and insignificant; yet, passing from these to his history, and to the account of his powers, we must confess the very great injustice we do him from want of consideration. We are obliged with the greatest surprise to acknowledge that those huge animals, the elephant, the rhinoceros, the lion, and the tiger, inhabiting the same woods, are still vastly his inferiors; and that the appearance of this small insect, *nay his very sound*, though he is not seen, occasions more trepidation, movement, and disorder, both in the human and brute creation, than would whole herds of those monstrous animals collected together, though their number was in a tenfold proportion greater than it really is. It is in size very little larger than a bee, and its wings,

which are broader than those of a bee, placed *separate, like those of a fly*. As soon as this plague appears, and their buzzing is heard, all the cattle forsake their food, and run wildly about the plain till they die worn out with fatigue, fright, and hunger. No remedy remains for the residents on such spots but to leave the black earth, and hasten down to the sands of Atbara, where they remain while *the rains last, this cruel enemy never daring* to pursue them further. What enables the shepherd to perform the long and toilsome journey across Africa is the camel, emphatically called the ship of the Desert. Though his size is immense, as is his strength, and his body covered with a thick skin defended with strong hair, yet still he is not capable to sustain the violent punctures this fly makes with his proboscis. He must lose no time in removing to the sands of Atbara, for when once attacked by this fly, his body, head, and legs break out *into large bosses*, which swell, break, and putrify, to the certain destruction of the creature. Even the elephant and rhinoceros, who, by reason of their enormous bulk, and the vast quantity of food and water they daily need, cannot shift to desert and dry places as the season requires, are obliged to roll themselves in sand and mire, which, when dry, coats them over like armour, and enables them to stand their ground against this winged assassin; yet have I found some of these tubercles upon almost every elephant and rhinoceros that I have seen, and attribute them to this cause."

On reading this account, we are most forcibly struck with many of the circumstances connected with the habits and appearances of the *Estridæ* (see Bor and Estrus). We have marked in italics those passages which seem to prove that the zimb is perfectly analogous to some of the *Estridæ*. Latreille also (*Règne Anim.* v. 500) expressly mentions the camel as being subject to the attacks of the *Estridæ*; and Mr. Hope has recently read, before the Entomological Society, an account of a larva of one of the same insects which attacks the rhinoceros. It is true that each species of *Estridæ* is peculiar to a particular quadruped; but we think by attributing part of Bruce's statement to the confusion prevailing in a desert by the maddened fury of a troop of rhinoceroses, for instance, on the appearance of *Estrus rhinoceros*, we shall not be very far wrong in considering the statement as a but slightly exaggerated account of circumstances seen by an eye-witness.

ZINC. This mineral occurs in a variety of forms, and is mostly found in collections of the metals under the name of calamine. Here it assumes the most beautiful forms, and when coloured by carbonate of copper presents a display of tints which are almost unrivalled in nature. It abounds in Somersetshire, Flintshire, and Derbyshire.

Both prismatic and rhomboidal calamine, when purified and roasted, are used in the fabrication of brass, which is a compound of zinc and copper, and the pure metal is also employed for a variety of purposes, the most important of which are comparatively new. Thus we find zinc, which was usually considered one of the hardest and most frangible of metals, rolled into thin plates, as a covering for houses and a variety of domestic utensils; and if its surface be kept bright it is especially fitted for the latter purpose, but the oxyde is injurious when allowed to corrode.

ZINGIBER (Gærtner). A useful genus of tuber-

ous-rooted herbs, having monandrous flowers, and belonging to *Scitamineæ*. This is the well-known ginger, so useful to the inhabitants of the countries where it grows wild, and also to every other part of the known world, as a wholesome spice. It is cultivated everywhere in India, and forms an important article in commerce. In Britain it is raised in very great perfection on hotbeds, for the purpose of making a preserve in its green and soft state.

ZIRCON. This rare and beautiful mineral derives its name from the French word *jargon*, which was originally applied to all those gems, which, on being cut and polished, had somewhat the appearance of the diamond. The common *Zircon* approaches to a grey colour, and is mostly procured from the island of Ceylon. The primitive form of *Zircon*, according to Haüy, is composed of two four-sided pyramids, applied base to base. The accompanying figures furnish good views of its ordinary crystallised forms.

Zircon is found in company with the hyacinth, with which it is frequently confounded, but from which it materially differs in its colour and crystallised form. From the diamond it is distinguished by its crystallisation, greater weight, and conchoidal fracture; and from most other gems by its peculiar power of refraction. These characteristics can only be easily indicated by absolute comparison; and this points out the great advantage of cabinet collections of specimens in mineralogical pursuits. Indeed, the great increase of knowledge in this branch of science, may be mainly traced to the increase of "natural history collectors," as the practical students in the great Book of Nature are usually called. Another circumstance, and one that should never be lost sight of in tracing the progress of mineralogy, is the facility for investigation on a large scale furnished by the vast gallery now opened to the public in the British Museum. We have there spread out before us many hundred thousands of specimens procured from every quarter of the globe; and if the descriptive accounts prefixed were but a little fuller, it would still more facilitate the researches of the student.

ZOEÆ (Bosc). A very curious genus of small crustaceous animals, respecting which great diversity of opinion has been entertained amongst crustaceologists: the carapax is large and nearly globose, armed with remarkably long spines in front and behind, as well as at the sides; the eyes are very large; and placed on footstalks; the apparent organs of locomotion are two pairs of large bifid articulated members; but a very careful examination discovers ten other rudimentary legs (the anterior pair being cheliferous) within the shells; the antennæ are four in number; and the abdomen long and furnished with a terminal apparatus for swimming. Latreille

has placed these insects, which are of very small size, amongst the branchiopodous *Entomostaca*; but Mr. J. V. Thompson has, in several memoirs, asserted that they are only the larvæ state of some of the crabs.

The assertions of this writer have need of much confirmation, and indeed Dr. Rathke, to whom Mr. Thompson is opposed *in toto*, has recently published a note, which will, we think, in conjunction with his announced Memoir, completely overthrow Mr. Thompson's statements, which are certainly made

without any of that precision which is so obviously requisite in such a matter. The species here figured is from Mr. Thompson's work; it is exceedingly minute (the size being indicated in the scroll), and was discovered in the sea near Cork, and is asserted by him to be the larva of the common edible crab.

ZYGODACTYLÆ. Birds which habitually have two toes to the front and two to the rear, without any reversing. They are the same with the *Grimperes*, *Sconsors*, or climbers of different authors. See the article *BIRD*, and the references therefrom, which are well worthy of attending to, as these are among the most peculiar, and therefore the most interesting, of all the birds.

ZYGENIDÆ (Stephens). A family of beautiful lepidopterous insects, placed by Linnæus with the *Sphinges*, on account of the similarity in the structure of the antennæ, but having a much nearer relation to some of the moths. The antennæ are generally thickened in the middle, and slightly pectinated, especially in the males. The wings, when at rest, are deflexed at the sides of the body, and very much varied in their colours, often offering glass-like spots; the abdomen is not tufted at the tip. The caterpillars are pilose, without any caudal appendage; they are not enclosed in a case, and feed on different leguminose plants. When full-grown, they form a silken cocoon, which they attach to the stem of different grasses, of a spindle-shaped appearance. They fly in the hot sunshine. Many of the species are exotic, few only being found in this country; these compose the two genera, *Zygæna* of Fabricius and *Procris* of Fabricius (*Ino*, Leach); the former comprises the Burnet moths (which are of a fine blue-black colour with scarlet spots), and the latter is composed of a single species known to collectors under the name of the green forerster (*Ino statice*, Leach). They are to be found in the summer months sporting on the wing, in the hottest sunshine, over grass, &c.

INDEX.

* * * This Index only contains such names as do not occur in the alphabetical arrangement of the work.

A

ABIES, *fir*, ii. 471
Abies Canadensis, *hemlock spruce fir*, ii. 725
Abies excelsa, *Norway spruce fir*, iii. 323
Abramis, *bream*, i. 627
Abu-harb, *antelopes*, i. 142
Acacia Arabica, *gum arabic tree*, ii. 693
Acacia vera, *Egyptian thorn*, ii. 394
Acer, *maple*, iii. 208
Acer pseudo-platanus, *sycamore*, iii. 747
Acherontia atropos, *death's-head moth*, ii. 243
Achillea anglica, *milfoil*, iii. 239
Achimedes coccinea, *trevirana*, iii. 811
Aconitum vulpina, *fox-bane*, ii. 532
Acouchy, *agouti*, i. 50
Acrydium, *tetys*, iii. 792
Aconitum napellus, *napellus*, iii. 311
Adda, *antelopes*, i. 143
Addax, *antelopes*, i. 141
Æthusa cynapium, *dog poison*, ii. 323;
fool's parsley, ii. 516
African lily, *agapanthus*, i. 45
African almond, *brabejum*, i. 617
Agaricus campestris, *mushroom*, iii. 295
Agate snails, *achatina*, i. 24
Agrostes stolonifera, *florin*, ii. 471
Ahu, *antelopes*, i. 139
Ahu, or *Tartarian roebuck deer*, ii. 259
Aira flexuosa, *hair-grass*, ii. 697
Air-bladder, *air-bag*, i. 57
Ajuga, *bugle*, i. 641
Alder, i. 70; *besulineæ*, i. 377
Algazel, *antelopes*, i. 142
Alligator pear, *persea*, iii. 423
Allium cepa, *onion*, iii. 348
Allium ophioscorodon, *rocambole*, iii. 576
Allium sativum, *garlic*, ii. 615
Allium porrum, *leek*, iii. 35
Allium schænoprasum, *chives*, ii. 31
Allseed, *radiola*, iii. 510
Althæa officinalis, *marsh-mallow*, iii. 211
Alopecurus pratensis, *fox-tail grass*, ii. 532
Aloë, *asphodeleæ*, i. 217
Aloe, *American*, *agave*, i. 48
Alpaca, *camel*, i. 680
Althæa rosea, *hollyhock*, ii. 766
Alucitida, *pterophorida*, iii. 504
Alyssum saxatile, *madwort*, iii. 74
Amanduvad, *fringillidæ*, ii. 546
Amaranthus blitum, *blite*, i. 517
NAT. HIST.—VOL. III.

Amarantus caudatus, *love-lies-bleeding*, iii. 64
Amaryllis reginae, *Mexican lily*, iii. 238
Amianthus, *asbestos*, i. 211
Amomum grana paradisi, *grains of paradise*, ii. 666
Ampelis, *cotinga*, ii. 155
Anacardiaceæ, *cassuvieæ*, i. 716
Anæma, *cavy*, i. 754
Ananapa sativa, *bromeliaceæ*, i. 630;
pine apple, iii. 472
Anarkak, *cetacea*, i. 787
Anas, *duck*, ii. 331
Anchusa, *bugloss*, i. 641
Andromeda, *ericeæ*, ii. 441
Anemone pulsatilla, *pasque flower*, iii. 415
Anethum graveolens, *dill*, ii. 281
Angel fish, *shark*, iii. 660
Angler lophius, iii. 59
Angora cat, *cat*, i. 739
Anguilla, *eel*, ii. 388
Anhinga, *darter*, ii. 238
Aniseed, *illicium*, ii. 824
Anodon, *anodonta*, i. 120
Anomia, *crania*, ii. 165
Anomia della, *placuna*, iii. 475
Anona cherimolia, *cherimoyer*, ii. 21
Anona squamosa, *sweet sop*, iii. 747
Anoplura, *parasitus*, iii. 387
Ant, *formicidæ*, ii. 516
Antilicidæ, *notoxidæ*, iii. 324
Anthobii, *glaphyridæ*, ii. 634
Anthophagus, *testeva*, iii. 45
Anthospermum, *Æthiopicum*, *amber tree*, i. 83
Antilopus, *antelopes*, i. 134
Ant Lion, *myrmelionidæ*, iii. 307
Apara brocket, *deer*, ii. 268
Ape, i. 161; *chimpansee*, 164; *orangutan*, 165; *siaming*, 167; *wouwou*, 168; *ouanko*, 169; *Gibbon* (black), 169; *Gibbon* (ash-coloured), 169
Aphidius losæ, *braconidæ*, i. 623
Apocynum androsaemifolium, *dog's-bane*, ii. 323
Aplous, *tryphoxylon*, iii. 816
Aptera, *aphaniptera*, i. 170
Aquila, *eagle*, ii. 349
Aquilegia vulgaris, *columbine*, ii. 93
Arachnides, *arachnida*, i. 184
Arachnoidæ, *arachnida*, i. 184
Aratoo (Goliath), *parrot*, iii. 409
Arbor vitæ, *conifera*, ii. 131
Arbutus, *ericeæ*, ii. 441
Arca cucullus, *cucullæ*, ii. 197
Archangel, *lamium*, iii. 23

Arctium, *burdock*, i. 646
Arctomys, *marmot*, iii. 208
Ardea, *heron*, ii. 726
Argyroneta, *diving water spider*, ii. 294
Ariel, *antelopes*, i. 140
Armadillo, i. 196; *peba*, 201; *mule*, 202; *toton verdadeiro*, 202; *mataco*, 202; *poyou*, 202; *the hairy*, 203; *pichiy*, 203; *tatouy*, 203; *giant* (or *twelve-banded*), 203
Arnee, *bos*, i. 566
Arnotto, *birineæ*, i. 505
Arrow-root, *maranta*, iii. 208
Artemia salinus, *branchipus*, i. 626
Artemisia Canadensis, *Canadian mugwort*, i. 684
Artemisia vulgaris, *mugwort*, iii. 292
Artichoke, *compositæ*, ii. 98
Artocarpus incisa, *bread-fruit*, i. 627
Arum dracontium, *green dragon*, ii. 673
Arum tribe, *aroidæ*, i. 195; *arum*, i. 210
Arundinaria macrosperma, *cane-brake*, i. 688
Ascalabota, *geckoidæ*, ii. 616
Asarum, *arsarabacca*, i. 210
Asemus, *conia*, ii. 129
Ash-leaved maple, *box elder*, i. 617
Asphodel, *asphodelus*, i. 218
Astarte, *crassina*, ii. 166; *compositæ*, ii. 102
Aster, *amellus*, i. 83; *compositæ*, ii. 102
Aster Tradescanti, *Michaelmas daisy*, iii. 238
Astragalus onobrychis, *sainfoin*, iii. 580
Astur, *hawk*, ii. 710
Asparagus, *asphodeleæ*, i. 218
Ateles (four-fingered monkeys) i. 229; *cosita*, 231; *black*, 231; *black handed*, 232; *marimonda*, 231; *chuya*, 232; *spider monkey*, 232; *miriki*, 232; *chamuk*, 232
Atragene zelanica, *Naravalia*, iii. 311
Atriplex hortensis, *orache*, iii. 351
Atropa belladonna, *deadly nightshade*, ii. 243
Attus, *sallicus*, iii. 603
Auk, *alca*, i. 66
Aurelia, *chrysalis*, ii. 36
Avena precox, *oat-grass*, iii. 341
Avena sativa, *oat*, iii. 340
Avena, *geum*, ii. 630
Avis, *aves*, *bird*, i. 389
Axis, *deer*, ii. 262

G G G

B

BABOON, i. 265; magot, 267; warden, 267; pig-tailed, or maimon, 267; black, or black ape, 268; little, 271; Guinea, 271; grey, or dog faced, 271; pig-faced, 271; mandrill, 272; drill, 273
Balm of Gilead, *ancyris*, i. 97; *dracocephalum*, ii. 327
Balm of Gilead tribe, *burseraceæ*, i. 647
Balsam apple, *cucurbitaceæ*, ii. 203
Balsamina hortensis, *garden balsam*, ii. 615
Baltimore oriole, *cassius*, i. 712
Bambusa latifolia, *nastus*, iii. 211
Baneberry, *actæa*, i. 28
Barbary family, *berberidæ*, i. 375
Barbadoes cherry, *malpighiaceæ*, iii. 95
Barbadoes gooseberry, *pereskia*, iii. 423
Barbet, or bearded bird, *bucco*, i. 686
Barbicaus, *bucco*, i. 637
Barbus, *barbel*, i. 287
Barley, *hordeum*, ii. 769
Barnacle-shell, *anatifa*, i. 105
Barringtonia, *stravadium*, iii. 727
Basella, *Malabar nightshade*, iii. 75
Basilisk lizard, *basiliscus*, i. 305
Bastard-balm, *melittis*, iii. 231
Bastard pimpinell, *centunculus*, i. 768
Bay laurel, *laurineæ*, iii. 33
Beaked or piked whale, *balæna*, i. 291
Bean, *taba*, ii. 448
Bear, 321; land or brown, 323; polar or sea, 325; black, 329; grisly, 332; barren ground, 335; spectacled, 336; Nepal or Thibet, 337; jungle, 337; common Indian, i. 337; Malay, i. 338
Bear-berry, *ericeæ*, ii. 441
Bearded titmouse, *bearded reed-bird*, i. 339
Bear's breech, *acanthus*, i. 16
Becafico, *flycatcher*, ii. 511
Beo-eater, i. 364; common, 368; Adanson's, 370; Mauritius, 370; Angola, 370; two-coloured, 370; Bullock's, 370; rod-headed, 371; Tarva, 371; eye-browed, 371; five-coloured, 371; green-coloured, 371; Sumatran, 371
Beech-tree, *cupulifera*, ii. 210
Beet-root, *chenopodeæ*, ii. 20
Bekr-el-wash, *antelopes*, i. 142
Bell-flower, *campanula*, i. 683
Bent-grass, *agrostis*, i. 52
Bertholetia excelsa, *Brasil nut*, i. 627
Betel, *piperaceæ*, iii. 474
Bib, *gadoidæ*, ii. 561
Bindweed family, *convolvulaceæ*, ii. 135
Bira brocket, *deer*, ii. 268
Birch, i. 388; *betulineæ*, 377
Bird of Paradise, i. 480; great or common, 484; royal or king, 485; red, 486; magnificent, 486; six-threaded, 487; small green, 487; white, 488
Birds'-nest orchis, *neottia*, iii. 314
Birds'-foot, *ornithopus*, iii. 354
Birds'-foot trefoil, *lotus*, iii. 63
Birthwort tribe, *aristolochiæ*, i. 194
Biscutella, *buckler mustard*, i. 639

Bison, i. 489; common, 491; American, 494
Bixa Orellana, *anotta*, i. 124
Black briony, *discoreæ*, ii. 283
Blackbird, *thrush*, iii. 795
Black fish, *scomberoidæ*, iii. 629
Black ape, or baboon, *baboon*, i. 268
Black briony, *tamea*, iii. 771
Black tail, *antelopes*, i. 140
Bladder-nut, *celastrineæ*, i. 761; *staphyleæ*, iii. 718
Bladder senna, *oolutea*, ii. 93
Blaesbok, or blissbok, *antelopes*, i. 147
Blatta orientalis, *cockroach*, ii. 73
Blaubok, *antelopes*, i. 145
Bleekbok, *antelopes*, i. 149
Blennius, *blenny*, i. 511
Blessed thistle, *compositæ*, ii. 99
Blind-worm, *anguis*, i. 112
Blitum, *chenopodeæ*, ii. 21
Blood-flower, *hemanthus*, ii. 697
Bloodwort, *sanguinaria*, iii. 605
Bluebottle, *cyanus*, ii. 225
Blue jay of America, *corvus*, ii. 151
Blue robin, *sylvia*, iii. 752
Boar fish, *scomberoidæ*, iii. 628
Boatbill, *caucroma*, i. 686
Bobac, *marmot*, iii. 209
Bocconia, *Macleaya*, iii. 72
Bois perdrix, *heisteria*, ii. 719
Bombax ceiba, *silk-cotton-tree*, iii. 683
Bombus, *humble-bee*, ii. 786
Bombyx, *goat-moth*, ii. 648
Bombyx mori, *silkworm*, iii. 683
Bombyx pityocampa, *onethocampa*, ii. 68
Bombyx processionea, *onethocampa*, ii. 67
Boneset, *compositæ*, ii. 102
Bonito, *scomberoidæ*, iii. 621
Booby, *gannet*, ii. 615
Boshbok, *antelopes*, i. 153
Botaurus, *bittern*, i. 497
Bottle-gourd, *cucurbitaceæ*, ii. 202; *lagenaria*, iii. 21
Bottle-head, beaked whale, *cetaceæ*, i. 798
Boxthorn, *licium*, iii. 71
Brahminy bull, *bos*, i. 561
Bramble-finch, *brambling*, i. 624
Brassica rapa, *rabe*, iii. 525
Bread-tree, *xyamia*, iii. 830
Breadfruit tribe, *artocarpeæ*, i. 209
Brill, *flat-fish*, ii. 502
Brine shrimps, *branchipus*, i. 626
Bristle-tooth, *chatodon*, ii. 2
Brocket, *pita*, *deer*, ii. 268; *apara*, 268; bird, 268
Bromus, *brome-grass*, i. 630
Brook-lime, *samolus*, iii. 603
Broom, *genista*, ii. 621
Broom-rape, *orobancheæ*, iii. 358
Brosimum alicastrum, *bread-nut*, i. 627
Bryonia dioica, *bryony*, i. 635
Bryony, *cucurbitaceæ*, ii. 203
Buccinum, *eburna*, ii. 376; *monoceros*, iii. 283; *purpura*, 507; *buccinum sulcatum*, *planaxis*, 475
Buchu family, *dioemeæ*, ii. 284
Buck bean, *menyanthes*, iii. 235
Buck-eye, *asculus*, i. 42
Buckwheat-tree, *mylocaryum*, iii. 304
Buffalo, *bos*, i. 563
Buffalo fish, *squamipennes*, iii. 769
Bulla, *ovula*, iii. 367

Bull antelope, *antelopes*, i. 151
Bull-head, *cottus*, ii. 156
Bullrush, *cyperaceæ*, ii. 233
Bully-tree, *achras*, i. 25
Bunium flexuosum, *earth-nut*, ii. 371
Bunting, *emberiza*, ii. 414
Burbot, *gadoidæ*, ii. 564
Burdock, *compositæ*, ii. 99
Burnet, *sanguisorba*, iii. 605
Bur-reed, *sparganium*, iii. 700
Bush antelope, *antelopes*, i. 144
Bush goat, *antelopes*, i. 144
Bushmaster, *crotalus*, ii. 180
Butcher-bird, *lanius*, iii. 25
Bute, *bussard*, i. 635
Butter-bur, *compositæ*, ii. 102
Butterfly, *papilio*, iii. 387
Butterfly-weed, *asclepiadeæ*, i. 212
Butterwort, *pinguicula*, iii. 473
Button-tree, *conocarpus*, ii. 132
Button weed, *spermaoceæ*, iii. 703
Button-wood, *cephalanus*, i. 768
Buxus sempervirens, *box-tree*, i. 617

C

Caama, *antelopes*, i. 149
Cacao tree, *hytneriaceæ*, i. 658
Cacalot, *cetaceæ*, i. 788
Cactææ, *opuntiaceæ*, iii. 351
Cainea, *cinchonaceæ*, ii. 53
Calabash, *cucurbitaceæ*, ii. 202
Calabash-tree, *oreocenta*, ii. 168
Caladium sequinum, *dumb cane*, ii. 346
Calamophilus biarmicus, *bearded reed-bird*, i. 339
Calceolaria pinnata, *slipper-wort*, iii. 694
Calebasia, *Adansonia*, i. 33
Calidris, *sanderling*, iii. 604
Callithrix, *monkey*, iii. 274
Caltha palustris, *marsh marigold*, iii. 211
Cambing outang, *antelopes*, i. 140
Camelus, *Camelidæ*, the camel family, *camel*, i. 671
Camelion, *Camelionidæ*, i. 680
Camelopardalis, *giraffe*, ii. 630
Campagnol, *arvicola*, i. 210
Camphor-tree family, *dipterocarpeæ*, ii. 290
Canada jay, *corvus*, ii. 152
Canary, *carduelis*, i. 704
Canary grass, *phalaris*, iii. 433
Cancer, *crab*, ii. 162
Cancer salinus, *branchipus*, i. 626
Candleberry myrtle, *myrica*, iii. 306
Cane-fly, *delphax*, ii. 270
Canis, *dog*, ii. 295
Cania, *antelopes*, i. 148
Cannabis sativa, *hemp*, ii. 725
Caoutchouc, *apocynæ*, i. 175; *Wilughbeia*, iii. 828
Cape buffalo, *bos*, i. 568
Cape Coast lily, *amaryllidæ*, i. 81
Caper family, *capparidæ*, i. 90
Capine capensis, *Cape phyllirea*, i. 690
Capparis spinosa, *caper-tree*, i. 90
Capra, *goat*, ii. 640
Caprimulgus, *nyctihalidon*, iii. 329
Capybara, *cavy*, i. 783
Caracal, *cat*, i. 744
Caragana, *halimodendron*, ii. 698

Carangus, scomberoides, iii. 628
 Cardinal, red, *fringillida*, ii. 542;
 blue, ii. 544; red-headed, ii. 544
Cardiospermum corindum, heart-seed,
 ii. 715
 Cardoon, *composita*, ii. 97
Carduelis spinus, aberdervine, i. 2
 Cariacon deer, *deer*, ii. 267
 Carica papaya, *papaw tree*, iii. 586.
 Caridea, *palamonida*, iii. 384
 Carnation, *caryophyllae*, i. 709
 Carob-tree, *ceratonia*, i. 772
 Carolina allspice family, *calycanthae*,
 i. 670
 Carp family, *cyprinoidae*, ii. 233
 Carpinus betulus, *hornbeam*, ii. 769
 Carrion crow, *corvus*, ii. 144
 Carrot, *daucus*, iii. 242
 Carum carui, *carraway*, i. 698
 Carya alba, *hickory-tree*, ii. 745
 Carya porcinus, *hognut*, ii. 766
 Caryocar nuciferum, *butter-nut*, i. 655
 Caryophyllus aromaticus, *clove-tree*,
 ii. 67
 Cashew nut, *anacardium*, i. 100
 Casheo family, *cassuvieae*, i. 716
 Castanea vesca, *chestnut*, ii. 23
 Castor fiber, *beaver*, i. 341
 Casuarina, *cassowary*, i. 715
 Catalpa longissima and syringifolia, *big-*
noniacea, i. 379
 Cat bird, *thrush*, iii. 799
 Catchfly, *silene*, iii. 683
 Cat-fish, *anarrhicas*, i. 101
 Cats-tail grass, *thlwm*, iii. 436
 Oattle-bird, *cow-bunting*, ii. 158
 Caurali, *grus*, ii. 676
 Caviadae, *cavy*, i. 752
 Cayenne pit-pat, *cassicus*, i. 713
 Cayenne warbler, *cassicus*, i. 713
 Cedar, *conifera*, ii. 129; of Lebanon,
 130; sacred Indian, 130; Virginian
 or red, 131; sharp, 131; white,
 131
 Cedrus Labani, *cedar of Lebanon*, i.
 760
 Centaurea benedicta, *blessed thistle*, i.
 514
 Cephalopoda, *cephalophora*, i. 768;
cryptodibranchiata, ii. 187
 Cerasus laurocerasus, *laurel cherry*,
 iii. 33
 Cerasus Lusitanica, *Portugal laurel*,
 iii. 497
 Cereal rye, *secale*, iii. 646
 Cereus grandiflorus, &c., *cactae*, i. 662
 Cerinthe major, *honeywort*, ii. 767
 Cermatia, *acutigera*, iii. 632
 Cervus, *deer*, ii. 246
 Chærrophyllum sativum, *chervil*, ii. 23
 Chaffinch, *fringillida*, ii. 545
 Chama, *cardita*, i. 698
 Chama, *cypricardia*, ii. 233
 Chamaelir, *isocardium*, ii. 884
 Chamois, *antelope*, i. 136
 Chamomile, *composita*, ii. 100
 Chamuk, *ateles*, i. 232
 Charadrius, *plover*, iii. 477
 Chat, *saricola*, iii. 609
 Chati, *cat*, i. 743
 Cheese-maggot, *tyrophaga*, iii. 817
 Cheetqula, *ciliurus*, i. 55
 Cheiromys Madagascariensis, *aye-aye*,
 i. 262
 Chetah, *cat*, i. 736

Chelmon, *squamipennes*, iii. 769
 Chêne noir, *bignoniaceae*, i. 379
 Chenopodium, *goosefoot*, ii. 664
 Chickara, *antelope*, i. 139
 Chickweed family, *caryophyllae*, i. 708
 Chiorium endivia, *endive*, ii. 425
 Chilidomium majus, *celandine*, i. 761
 Chimpansee, *ape*, i. 164
 China-asters, *callisterna*, i. 668
 Chinche, *marten*, iii. 224
 Chinchilla, *chinchillidae*, ii. 26
 Chinese mugwort, *composita*, ii. 101
 Chionanthus Virginica, *fringe tree*, ii.
 536
 Chirocephalus, *branchipus*, i. 626
 Chiru, *antelope*, i. 137
 Choko, *sechium*, iii. 646
 Chondrilla juncea, *gum suocory*, ii. 693
 Chough, *corvus*, ii. 150
 Christ's-thorn, *paliurus*, iii. 384
 Chrysanthemum leucanthemum, *oxeye-*
daisy, iii. 380
 Chrysanthemum, *composita*, ii. 102
 Chrysophyllum splendens, *nycleresition*,

 Cumindia, *tarus*, iii. 785
 Cupressus disticta, *schubertia*, iii. 613
 Cupressus Lusitanica, *glauca*, cedar of Goa, i. 760
 Curassow, ii. 210; wattled, ii. 211; crested, ii. 211; lumped, ii. 212
 Currant, *ribes*, iii. 575
 Currant hornet sphynx, *ægerieda*, i. 41
 Curruca atricapilla, *blackcap*, i. 506
 Curruca luscinia, *nightingale*, iii. 316
 Curruca garrula, *babillard*, i. 264
 Crenia, *diaphora*, ii. 275
 Cydonia vulgaris, *quince*, iii. 508
 Cygnus, *swan*, iii. 741
 Cymbidium, *cirrheæ*, ii. 55
 Cynara cardunculus, *cardoon*, i. 699
 Cynara scolymus, *artichoke*, i. 205
 Cynosurus cristatus, *dog's-tail grass*, ii. 323
 Cypress, *conifera*, ii. 131
 Cypress-leaved lavender cotton, *composita*, ii. 102
 Cyprinus, *bream*, i. 627
 Cyprinus gobio, *gudgeon*, ii. 677
 Cyrilla pulchella, *Trevirana*, iii. 811

D

Dan, *flat-fish*, ii. 501
 Dactylis glomeratus, *cock's-foot grass*, ii. 73
 Dahlia, *composita*, ii. 102

Daisy, *composita*, ii. 102
 Dama, *antelope*, i. 143
 Dammar-pine, *conifera*, ii. 131
 Dandelion, *composita*, ii. 100
 Dart-snake, *acontia*, i. 26
 Dascillus, *atopa*, i. 245
 Dasypus, *armadillo*, i. 196
 Date plum, *diospyrus*, ii. 284
 Day lily, *hemerocallis*, ii. 723
 Dead nettle, *archangel*, i. 188
 Deciduous cypress, *schubertia*, iii. 613
 Deer, ii. 246; rein-deer, 249; elk, 251; stag or red deer, 254; fallow, 257; roebuck, 258; Ahu or Tartarian roebuck, 259; Nepal stag, 260; great rusa, 260; samver of Bengal, 260; Malay rusa, 261; Mariana rusa, 261; rusa of Timor, 262; spotted axis, 262; Nepal muntjak, 263; Wapiti, 263; north-western stag, 264; Virginian deer, 265; large-eared, 266; long-tailed, 266; guazupuco, 266; guazeli, 267; cariacou, 267; pita brocket, 268; apara brocket, 268; bira brocket, 268; fossil, 268
 Delphinium, *larkspur*, iii. 33
 Dendrocopos, *picuculi*, iii. 438
 Desmodium gyrans, *moving plant*, iii. 290
 Devil's coach-horse, *brachelytra*, i. 618
 Dianthus caryophyllus, *clove*, ii. 65
 Diard's Java cat, *cat*, i. 744
 Didus, *dodo*, ii. 295
 Didymocarpeæ, *cyrtandraceæ*, ii. 234
 Digitalis purpurea, *foxglove*, ii. 532
 Dimorpha, *astata*, i. 228
 Diomedea, *albatross*, i. 60
 Dodder, *convolvulacææ*, ii. 136
 Dodder, *cuscuta*, ii. 218
 Dog, ii. 298; wild dog of Nepal, 304; Pariah, 304; Malay, 304; Australian or Dingo, 305; African, 305; South American, 305; North American, 306; Highland greyhound, 306; Irish wolf-hound, 307; spotted Dalmatian or Hungarian, 307; French matin, 307; greyhound, 308; Scotch greyhound, 308; Turkish greyhound, 308; bloodhound, 308; staghound, 309; talbot, 310; foxhound, 310; harrier, 310; beagle, 310; Scotch terrier, 311; English terrier, 311; spaniel springer, 311; alpine spaniel, 311; water spaniel, 312; setter, 313; Spanish pointer, 313; English pointer, 313; Russian pointer, 314; Newfoundland, 314; Siberian, 315; Iceland, 315; Greenland, 315; Esquimaux, 315; shepherd's, 315; cur, 317; lurcher, 318; leymmer, 318; tumbler, 318; turnspit, 319; bull-dog, 320; mastiff, 321; ban-dog, 322; Cuban mastiff, 322
 Dog-fish, *shark*, iii. 651; picked, 657
 Dog's-tail grass, *cynosurus*, ii. 232
 Dog-poison, *althusa*, i. 43
 Dogwood, *cornææ*, ii. 140
 Dolphin, *cetacea*, i. 789, 791
 Doronicum pardalianches, *leopard's bane*, iii. 41
 Dory, *scomberoidææ*, iii. 628
 Dove, turtle, *pigeon*, iii. 462; American ground, 468; rust-coloured

ground, 469; picui ground, 469; bronze-winged ground, 469; white-bellied ground, 470; copper-coloured ground, 470; white-fronted ground, 471; blue-headed ground, 471; ca-runculated ground, 471; wattled ground, 472; Nicobar ground, 472
 Dragon flies, *agronida*, i. 81
 Dragon lizard, *lizard*, iii. 53
 Drill, *baboon*, i. 273
 Drongo, *edolius*, ii. 386
 Drosera rotundifolia, *sundew*, iii. 781
 Duck, ii. 331; wild or mallard, 335; summer, 339; eider, 345
 Dugong, *cetacea*, i. 794
 Dunlin, *tringa*, iii. 813
 Dyer's wood, *crucifera*, ii. 183; *resadacea*, iii. 564
 Dzeren, *antelope*, i. 138
 Dziggiti, *horse*, ii. 782

E

Eagles, ii. 349; golden, 353; little or spotted, 357; wedge-tailed, 358; ash coloured, 358; white-headed, 360; osprey, 364; great American, 368; harpy, 369; caracara, 370; Chilian, 370; South African, 370; whitish African, 370; vociferous or screaming, 371; Pondicherry, 371
 Earth-wolf, *ard-wolf*, i. 1
 Earwig, *forficula*, ii. 516
 Eceoptogaster, *scolytus*, iii. 617
 Echinos sphaerocephalus, *globe thistle*, ii. 635
 Eft, *salamander*, iii. 586
 Elaeodendron orientalis, *olive-wood*, iii. 347
 Elecampane, *composita*, ii. 102
 Electric eel, *gymnotus*, ii. 694
 Elder, *caprifoliaceæ*, i. 92
 Elder-tree, *sambucus*, iii. 603
 Eledons, *boleophagus*, i. 541
 Elephant beetle, *dynastes*, ii. 347
 Echinos foot, *dioscoreæ*, ii. 283
 Elephas, *elephant*, ii. 397
 Eleutherata, *coleoptera*, ii. 76
 Elk, *deer*, ii. 251
 Elymus arenarius, *lyme grass*, iii. 71
 Enchanter's nightshade family, *circææ*, ii. 54
 Endive, *composita*, ii. 99
 Engraulis, *anchovy*, i. 105
 Epidendron vanilla, *vanilla*, iii. 820
 Epimachus, *promerops*, iii. 498
 Epimedium alpinum, *barren-wort*, i. 300
 Equine antelope, *antelope*, i. 145
 Equisetum palustre, *horse-tail*, ii. 785
 Equus, *horse*, ii. 770
 Equus asinus, *ass*, i. 219
 Erica, *heath*, ii. 715
 Erinaceus, *hedgehog*, ii. 715
 Ermine, *marten*, ii. 218
 Erodium, *heron's bill*, ii. 736
 Ervum lens, *lentil*, iii. 41
 Erythronium dens canis, *dogs-teeth violet*, ii. 323
 Esculapian serpent, *coluber flavescens*, ii. 92
 Eucalyptus robusta, *gum-tree*, ii. 693
 Eugenia Malaccensis, *Malay apple*, iii. 94
 Eugenia, *stravadium*, iii. 727

Eupatorium cannabinum, *hemp agrimony*, ii. 735
Eupatorium, ozothamnus, iii. 383
Euphorbia caput Medusæ, *medusa*, iii. 228
Euphorbia lathyris, *caper spurge*, i. 690
European goat sucker, *nyctichelidon*, iii. 330
Exocoetus, *flying fish*, ii. 511
Exophthalmus, *campylus*, i. 684
Eyebright, *euphrasia*, ii. 447

F

Fagus castanea, *chestnut*, ii. 23
Fagus sylvatica, *beech tree*, i. 363
Falcon, *falcon*, ii. 449
Fallow-deer, *deer*, ii. 257
Fan-palm, *chamærops*, ii. 6
Fan-tail, *rhipidura*, iii. 574
Father-lasher, *cottus*, ii. 157
Feunel grass, *stipa*, iii. 726
Felis, *felinae*, *cat*, i. 718
Felwort, *swertia*, iii. 747
Feunel, *ferula*, ii. 469
Fern, *filices*, ii. 471
Ferret, *marten*, iii. 216
Ferula communis, *giant fennel*, ii. 630
Festuca, schedonorus, iii. 613
Feverfew, *compositæ*, ii. 101; *tyranthum*, iii. 507
Fiens, *artocarpa*, i. 209
Field-fare, *thrush*, iii. 796
Fig, *artocarpa*, i. 209
Fig-marigold, *ficoidea*, ii. 469
File-fish, *balistes*, i. 293
Finch, finch family, *fringillidæ*, ii. 536; *lazuli nonpareil*, 537; *painted nonpareil*, 537; *purple*, 538; *alpine snow*, 545; *American snow*, 545; *Whidah*, 546
Finger grass, *digitalis*, ii. 281
Finner, *balana*, i. 289
Florin-grass, *agrostis*, i. 52
Fir, *abies*, i. 4
Fir family, *conifera*, ii. 129
Fish lice, *ostigides*, i. 666
Fishing crow, *corvus*, ii. 153
Five-banded gado, *gadoidæ*, ii. 564
Flat pea, *platylobium*, iii. 476
Flea bane, *compositæ*, ii. 102
Flea bane, *conysa*, ii. 136
Flesh fly, *blue bottle*, i. 533
Fleur-de-lys, *iris*, ii. 884
Flowering ash, *ornus*, iii. 358
Flowering rush tribe, *butomia*, i. 651
Fly, *musca*, iii. 294
Flying cat, *galeoptheus*, ii. 567
Flying squirrel, *pteryomys*, iii. 503
Fool's parsley, *athusa*, i. 43
Forficula auricularia, *earwig*, ii. 375
Fork-head, *gadoidæ*, ii. 565
Formica, *ant*, i. 124
Fossil deer, *deer*, ii. 268
Foxglove, *digitalis*, ii. 281
Four-striped snake, *coluber quadrilineatus*, ii. 92
Francolin, *gallinidæ*, ii. 599
Fraxinella, *dictamnus*, ii. 276
Fraxinus excelsior, *ash tree*, i. 213
Fringilla montefringilla, *brambling*, i. 624

Fringe tree, *chionanthus*, ii. 27
Fringilla spinus, *aberdavine*, i. 2.
Frogs and frog-like animals, *batrachia*, i. 307
Frog fishes, *chironactes*, ii. 27
Fulmar, *petrel*, iii. 427
Furze wren or Dartford warbler, *caruca*, ii. 217

G

GADWALL, *duck*, ii. 337
Gale, *myrica*, iii. 306
Galeobdolon luteum, *dead nettle*, ii. 243
Galeum sparine, *cleavers*, ii. 63
Galgulus, *roller*, iii. 576

Globe thistle, *echinops*, ii. 384
Glory of Kent, *endromis*, ii. 426
Glutton, *gulo*, ii. 689
Gnaphalium, *everlasting*, ii. 448
Gnat, *culicidæ*, ii. 203
Gnu, *antelopes*, i. 150
Goat's-beard, *compositæ*, ii. 100; *tragopogon*, iii. 811
Goatsucker, *nyctichelidon*, iii. 331; *scissor-tailed*, 336; *collared*, 337
Goby family, *gobioidæ*, ii. 648
Golden-rod, *compositæ*, ii. 102; *solidago*, iii. 699
Golden green mole, *chrysochloris*, ii. 39
Golden thistle, *scolumus*, iii. 617
Goldfinch, *carduelis*, i. 699; *American*, 702; *Chinese*, 703
Gomphia, *button flower*, i. 655
Good Henry, *bonus Henricus*, i. 550
Goosander, *mergus*, iii. 235
Gouseberry, *ribes*, iii. 575
Goosypium, ii. 664; *cotton*, 156; *malvaceæ*, 95

Goosefoot family, *chenopodeæ*, ii. 19
Gourd family, *cucurbitaceæ*, ii. 200
Goui, *Adansonia*, i. 33
Grackle, *gracula*, ii. 664
Grampus, *cetaceæ*, i. 791
Grande vache brune, *antelopes*, i. 144
Grand lory of Latham, *parrot*, iii. 405
Gratiola officinalis, *hedge hyssop*, ii. 719
Grey or dog-faced baboon, *baboon*, i. 271
Grias cauliflora, *anchovy pear*, i. 107
Grison, *gulo*, ii. 690
Grosbeak, green, *fringillidæ*, ii. 540; *haw*, 541; *evening*, 541
Groundsel, *compositæ*, ii. 102; *senecio*, iii. 646
Groundling, *cobitis*, ii. 70
Grouse, *gallinidæ*, ii. 603; *black cock*, 603; *duky*, 604; *wood*, 604; *cock of the plains*, 605; *Richardson's*, 605; *sharp-tailed*, 606; *Franklin's*, 606; *Canada spotted*, 606; *red*, 606; *hazel*, 606; *ruffed*, 606; *willow*, 607; *rock*, 607
Gryllotalpa, *mole cricket*, iii. 254
Gryllus acrida, *truxales*, iii. 316
Grysbok, *antelopes*, i. 152
Guaiacum, *rutaceæ*, iii. 579
Guan, *gallinidæ*, ii. 586
Guanoco, *camel*, i. 679
Guaphalium, *compositæ*, ii. 102
Guazeli, *deer*, ii. 267
Guazupuco, *deer*, ii. 266
Guelder-rose, *caprifoliaceæ*, i. 692
Guib, *antelopes*, i. 144
Guinea baboon, *baboon*, i. 271
Guinea-fowl, *gallinidæ*, ii. 583; *crested*, 584; *mitred*, 585
Guinea-pig, *cavy*, i. 754
Gull, ii. 679; *black-backed*, 681; *burgomaster*, 681; *common*, 681; *kittiwake*, 682; *silvery*, 682; *ivory*, 683; *laughing*, 683; *Iceland*, 684; *smaller black-backed*, 684; *Sabine's*, 685; *little*, 685; *ash-headed*, 685
Gymnadenia viridis, *frog orchis*, ii. 553
Gymnolepas, *cinaræ*, ii. 53
Gyrinus natator, *whirl-wig*, iii. 828

H

HADDOCK, *gadoidæ*, ii. 560
Hamatoxylon Campechianum, *logwood*, iii. 58
Hag, *lamprey*, iii. 24; *myrene*, 309
Hake, *gadoidæ*, ii. 563
Hair-streaks, *thecla*, iii. 793
Hairy armadillo, *armadillo*, i. 203
Halibut, *flat-fish*, ii. 501
Hamiltonia oleifera, *oil nut*, iii. 346
Hamster, *cricetus*, ii. 168
Hare, ii. 701; *common*, 703; *Alpine*, 704; *Irish*, 705; *black tailed*, 706; *Tolai*, 707; *Egyptian*, 707; *Virginian*, 707
Harled, *duck*, ii. 343
Harvest spiders, *phalangidæ*, iii. 431
Hawkbit, *apargia*, i. 161
Hawk-owl, *owl*, iii. 367
Hawthorn, *crataegus*, ii. 166
Hazel nut, *cupulifera*, ii. 210
Heather or ling, *ericeæ*, ii. 441
Heath tribe, *ericeæ*, ii. 440
Hedge-mustard, *crucifera*, ii. 182; *erisimum*, 444

Hedge-sparrow, chanter or accentor, *accentor*, i. 18
 Helleborus hyemalis, *eranthus*, ii. 440
 Hedyssarum movens, *moving plant*, iii. 290
 Helleborus niger, *Christmas rose*, ii. 84
 Helianthus tuberosus, *Jerusalem artichoke*, iii. 2
 Helopii, *helopida*, ii. 723
 Helix, *bulimus*, i. 642; *cyclostoma*, ii. 228; *janthina*, 818; *planorbis*, iii. 475
 Helix amarula, *melania*, iii. 229
 Helix Halioldea, *sigaretus*, iii. 683
 Helix ringens, *anostoma*, i. 124
 Hemerocallis, *day lily*, ii. 243

 Ovis, *sheep*, iii. 662
 Ounko, *ape*, i. 169
 Owl, iii. 367; little, 371; feathery-footed little, 371; hawk, 371; great tufted, or eagle, 373; long-tufted, 374; barred, 375; short-tufted, 375; scope-tufted, 376; African-tufted, 376; tawny, 377; barn or white, 378
 Oxyrhinchus, *matideæ*, iii. 75
 Ox, *bos*, i. 552
 Oxycooccus palustris, *cranberry*, ii. 164
 Oxyuri, *proctotrupidæ*, iii. 498

P

Painted lady, *Cynthia*, ii. 282

Palæmon serratus, *prawn*, iii. 497
 Pallah, *antelope*, i. 151
 Palmetto, *sabal*, iii. 579
 Pamphilius, *lyda*, iii. 71
 Panax quinquefolia, *ginseng*, ii. 630
 Panda, *ailurus*, i. 55
 Paudiella Suecica, *blue breast*, i. 533
 Panicum colonum, *panic grass*, iii. 386
 Panther, *cat*, i. 735
 Papyrus, *cyperaceæ*, ii. 232
 Paradise, *birds of paradise*, i. 480
 Parakeet (golden crested) *parrot*, iii. 397; *scaly*, 397; party coloured, 397; Carolina, 397; solstitial, 399; Alexander's ring, 400; Pondicherry, 400; Bengal, 400; yellow ringed, 400; yellow shouldered, 400; double collared, 401; ring, 401; Molucca, 401; Swainson's, 401; bordered wing, 402; flat tailed, 402; Lichtenstein's, 402; Latham's, 403; many coloured, 403; New Zealand, 403
 Parinarium excelsum, *Guinea plum*, ii. 679
 Paris quadrifolia, *herb Paris*, i. 726
 Paper nautilus, *argonauta*, i. 191
 Parnassus, *doritis*, ii. 324
 Parraqua, *gallinidæ*, ii. 589
 Parrot, iii. 387; Patagonian macaw-parrot, 397; common grey, 403; common green, 405; festive, 405; robust, 406; blue crowned little, 414; grand, 414
 Partridge, *gallinidæ*, ii. 596; red legged, 598; Greek, 599; Heya, 599; yellow bellied, 599; eyed, 599; Pondicherry, 600; North American, 600; Virginian, 600
 Parus, *tit* or *titmouse*, iii. 805
 Parus caudatus, *bottle tit*, i. 611
 Parus cæruleus, *blue cap*, i. 534
 Passer domesticus, *sparrow*, iii. 700
 Pastinaca sativa, *parsnip*, iii. 415
 Patagonian penguin, *ablenodytes*, i. 178
 Patella, *crepigula*, ii. 167; *fissurella*, 496
 Patella fissura, *emarginula*, ii. 414
 Patella lepas, *concholepas*, ii. 103
 Patella unguis, *lingula*, iii. 50
 Patella ungarica, *pilolepis*, iii. 472
 Pauxi, *gallinidæ*, ii. 585
 Paycul, *atopa*, i. 245
 Pavia, *æsculus*, i. 42
 Peacock, *gallinidæ*, ii. 579; Thibet, 581; Japan, 581
 Pebs, *armadillo*, i. 201
 Peccary, *sus*, iii. 739
 Pecten maximus, *scallop-shell*, iii. 611
 Pelandok, *musk*, iii. 298
 Pellitory, *compositæ*, iii. 100
 Pepper, *pipereacæ*, iii. 474
 Pepper-wort, *crucifera*, ii. 183
 Perca, *perch*, iii. 422
 Perca scandena, *anabas*, i. 98
 Pernys, *amphipoda*, i. 95
 Persian cat, *cat*, i. 739
 Persica levis, *nectarine*, iii. 313
 Persica vulgaris, *peach*, iii. 416
 Peruvian bark, *cinchonaceæ*, ii. 49
 Petite vache brune, *antelope*, i. 144
 Petrocles, *gallinidæ*, ii. 607

Petromyzon, *lamprey*, iii. 23
 Phalacrocorax, *cormorant*, ii. 138
 Phalena, *goat-moth*, ii. 648
 Phalena tinia, *tinia*, iii. 803
 Phaleno tortrix, *tortricida*, iii. 808
 Phalaris canariensis, *canary grass*, i. 684
 Phascolaretus, *koala*, iii. 16
 Phascolus vulgaris, *kidney bean*, iii. 13
 Phasianus argus, *argus*, i. 193
 Pheasant, *gallinida*, ii. 576; golden, 577; silver, 578; ring-necked, 578; Reeve's, 579; nepal, 582; crested, 590
 Phitis, *carychium*, i. 708
 Phleum pratense, *cat's-tail grass*, i. 749
 Phoca, phocidæ, *seal*, iii. 632
 Phœnicopterus, *flamingo*, ii. 497
 Phoenix dactylifera, *date palm*, ii. 242
 Phormium tenax, *flax lily*, ii. 504
 Physic nut-tree *Jathropha*, iii. 1
 Pichiy, *armadillo*, i. 203
 Pigeon, iii. 447; pointed-tailed, 451; aromatic, 451; parrot, 451; commander, 451; Abyssinian, 451; purple-crowned, 451; magnificent, 452; pheasant, 452; chestnut shouldered, 452; goura, 453; ringed, 453; double-crested, 454; wood, 457; rock, 457; carrier, 460
 Pig-faced baboon, *baboon*, i. 271
 Pig-tailed baboon, *baboon*, i. 268
 Pika, *hare*, ii. 708; Alpine, 708; grey, 708; calling, 709
 Pike, *esox*, ii. 445
 Pilchard, *herring*, ii. 741
 Pillwort, *ficaria*, ii. 469
 Pilot-fish, *scomberoida*, iii. 624
 Pinella, *burnet eari-frage*, i. 646
 Pinche, *monkey*, iii. 282
 Pine-apple family, *bromeliaceæ*, i. 630
 Pink, *caryophyllæ*, i. 709
 Pinus cedrus, *cedar of Lebanon*, i. 760
 Pipe-fish, *syngnathus*, iii. 762
 Pipra, *manakin*, iii. 203
 Pique-bœuf, *buphaga*, i. 644
 Piatachie, *lentiscus*, iii. 41
 Piatachie lentiscus, *mastic tree*, iii. 228
 Piatachie tree, *cassuviea*, i. 717
 Pisum sativum, *pea*, iii. 416, 474
 Pita brocket, *deer*, ii. 268
 Pithecus, *ape*, i. 161
 Plantain-eater, *touraco*, iii. 810
 Plane-tree, *platanus*, iii. 476
 Platalea, *spoonbill*, iii. 707
 Platicurii, *parrot*, iii. 414
 Platysoma, *cucujida*, ii. 197
 Pleuronectes, *flat-fish*, ii. 498
 Plover, iii. 477; dotterel, 479; ring, 480; Kentish, 481; crowned, 481; black-headed, 481; spur-winged, 482; hooded, 482; Cayenne, 482; wattled, 482; double-collared, 482; red capped, 482; Wilson's, 482; kildeer, 483; black-bellied, 484
 Poa pratensis, *meadow-grass*, iii. 228
 Pochard, red-headed, *duck*, ii. 341; canvass-back, 342; white-eyed, 343; tufted, 343; red crested, 343
 Podiceps, *grebe*, ii. 668
 Podophyllum peltatum, *May-apple*, iii. 228

Podoa, *grebe-coot*, ii. 672
 Pœonia suffruticosa, *moutan*, iii. 290
 Pogonophorus, *leistus*, iii. 36
 Pollack, *gadoida*, ii. 563
 Polecat, common *marten*, iii. 215; Polish, 216; Siberian, 217; Japanese, 220; African, 220; Madagascar, 220; Cape, 220
 Polygala vulgaris, *milkwort*, iii. 239
 Polygonatum vulgare, *Solomon's seal*, iii. 699
 Polygonum fagopyrum, *buck-wheat*, i. 639
 Pomme de prairie, *psoralea*, iii. 501
 Pond-weed, *potamogeton*, iii. 497
 Poplar, *populus*, iii. 497
 Poppy, *papaveraceæ*, iii. 386
 Populus alba, *abele tree*, i. 2
 Porbeagle, *shark*, iii. 655
 Porpoise, *cetaceæ*, i. 790
 Potentilla fruticosa, *cinquefoil*, ii. 54
 Poterium sanguisorba, *burnet*, i. 646
 Pouched badger, *perameles*, iii. 421
 Poultry, and birds resembling poultry, *gallinidæ*, ii. 568
 Pout, *gadoida*, ii. 561
 Poyou, *armadillo*, i. 202
 Pratincole, *glareola*, ii. 634
 Pride, *ammocates*, i. 92
 Primula elatior, *oxlip*, iii. 380
 Primula veris, *vulgaris cowslip*, ii. 162
 Procœllaria, *petrel*, iii. 427
 Procyon, *raccoon*, iii. 508
 Proteles cristata, *aard-wolf*, i. 1
 Proteus Mexicanus, *axoloti*, i. 262
 Prunus domestica, *plum*, iii. 484
 Prunus inositia, *bullace tree*, i. 643
 Prunus myrobalana, *myrobalan plum*, i. 308
 Psittacus, psittacidæ, *parrot*, iii. 387
 Psychotria, *cinchonaceæ*, ii. 57
 Ptarmigan, *gallinidæ*, ii. 607
 Pteris aquilina, *brake*, i. 624
 Pteroglossus, *aracari*, i. 183
 Pterophorites, *ptero-phorida*, iii. 504
 Puffin, ash-coloured, *petrel*, iii. 429; sooty, 430
 Puffin, *fratercula*, ii. 534
 Pulicidæ, *pulex*, iii. 504
 Pulmonaria officinalis, *lungwort*, iii. 65
 Puma, *cat*, i. 737
 Pumpkin, *cucurbitaceæ*, ii. 202
 Punica granatum, *pomegranate*, iii. 496
 Purre, *tringa*, iii. 813
 Puss-moth, *cerura*, i. 778
 Pyrus aucuparia, *mountain ash*, iii. 290
 Pyrus malus, *apple*, i. 175
 Pyrus sativa, *pear*, iii. 417

Q

Quagga, *horse*, ii. 783
 Quail, Virginian, *gallinidæ*, ii. 600; californian, 601; common, 601; Chinese, 602; New Holland, 602
 Quercus robur, *oak*, iii. 340
 Quince, *cydonia*, ii. 229
 Quicksilver, *mercury*, iii. 235

R

Rabbit, *hare*, ii. 705; Siberian, 707

Raccoon rat, *eupromys*, i. 93
 Radish, *crucifera*, ii. 183; raphanus, iii. 525
 Rail, *rallus*, iii. 521; water, 522; clapper, 523; Virginian, 523; laughing billed, 524; gigantic, 524
 Ramoon trees, *trophis*, iii. 816
 Rana, *frog*, ii. 547
 Ranunculus bulbosus, *butter cup*, i. 651
 Ranunculus acris, *crowfoot*, ii. 181
 Rape or cole-seed, *crucifera*, ii. 183
 Rat, iii. 526; brown, 532; black, 535; Sumatra, 535; Caraco, 535; Alexandrian, 536; Iceland, 536; water, 539
 Rat-bane, *chailletiacæ*, ii. 4
 Ratel, *gulo*, ii. 692
 Rat-hares, *hare*, ii. 707
 Rattan-seed, *calamus*, i. 664
 Rattlesnake, *crotalus*, ii. 177
 Rat's-bane, *apocynæ*, i. 174
 Raven, *corvus*, ii. 143
 Ray, *raia*, iii. 510; starry, 517; bordered, 518; small-eyed, 518; sting, 519
 Ray-grass, *brome-grass*, i. 630
 Razor-bill, *alca*, i. 66
 Recurvirostra, *avocet*, i. 258
 Redbreast, *sylvia*, iii. 750
 Red Jamaica dogwood, *pisocidia*, iii. 474
 Redbreasted merganser, *mergus*, iii. 237
 Red mullet, *mullus*, iii. 292
 Redstart, *sylvia*, iii. 751; black, 752
 Redwing, *thrush*, iii. 767
 Reed bunting, *tringillidæ*, ii. 538
 Reed pheasant, *bearded reed-bird*, i. 339
 Rein-deer, *deer*, ii. 249
 Reibok, *antelopes*, i. 155

 Squallus, *squalidæ*, *shark*, iii. 648
 Squash, *cucurbitacæa*, ii. 202
 Squill, *asphodelæa*, i. 218; *scilla*, ii.
 614

T

Staff-tree family, *celastrinæ*, i. 761
 Stag, or red deer, *deer*, i. 254
 Stag-beetle (small), *dorcus*, ii. 324
 Staphylea pinnata, *bladder-nut*, i. 507
 Star-fish, *asterias*, i. 228
 Star-gazer, *uranoscopus*, iii. 819
 Star-thistle, *compositæ*, ii. 99
 Starry skin, *asterodermus*, i. 229
 Starwort, *aster*, i. 228
 Steedman's antelope, *antelopes*, i. 145
 Stellere, *cetacea*, i. 795
 Stenobok, *antelopes*, i. 152
 Stenopteryx, *craterina*, ii. 167
 Stilt, *himantopus*, i. 745
 Stitchwort, *stellaria*, iii. 721
 St. John's wort, *hypericynæ*, ii. 816
 Stock, *mathiola*, iii. 228
 Stone-crop, *crassulacæ*, ii. 166
 Stone-crop, *sedum*, iii. 646
 Stone-grig, *annomacæ*, i. 92
 Stork, *ciconia*, ii. 44
 Strawberry, *fragaria*, ii. 532
 Strawberry-tree, *arbutus*, i. 188
 Strix, strigide, *owl, owl family*, iii. 367
 Struthio, Struthionidæ, *ostrich*, iii. 360
 Strychnos, *apocynæ*, i. 174
 Strychnos nux-vomica, *vomit-nut*, iii. 823
 Stuartia malachodendron, *malachodendron*, iii. 75
 Sturgeon, *acipenser*, i. 18
 Sturnus, *starling*, iii. 718
 Subularia, *owl-wort*, i. 261
 Succoria, *compositæ*, ii. 99
 Sucker, *discobolus*, ii. 291
 Suctoria, *aphaniptera*, i. 170
 Sugar-cane, *saccharum*, iii. 580
 Sula, *gannet*, ii. 611
 Sultana hen, *gallinule*, ii. 609
 Sumach, *casuarina*, i. 717
 Sumatra cat, *cat*, i. 744
 Sundew family, *droseraceæ*, ii. 330
 Sunflower, *compositæ*, ii. 101; *helianthus*, 719
 Sunstone, *adularia*, i. 41
 Supula aquaria, *aspergillum*, i. 216
 Sur mullet, *mullus*, iii. 292
 Swallow-nut, *rhizoboleæ*, iii. 574
 Swallow, *hirundo*, ii. 754; chimney, 756; Java, 761; American chimney, 762; barn, 763; white-bellied American, 764; white-breasted, of Paraguay, 765; domestic, of Paraguay, 765
 Swallow-wort, *asclepiadeæ*, i. 212
 Sweet basil, *ocymum*, iii. 341
 Sweet flag, *acorus*, i. 26
 Sweet flag, *aroidæ*, i. 196
 Sweet leaf, *symplocobolæ*, iii. 761
 Sweet potato, *convolvulacæ*, ii. 136
 Swietenia mahogani, *mahogany tree*, iii. 74
 Swift, *hirundo*, ii. 759; ruffed, 761; great Chinese, 761; great, 761
 Swift foot, *cursorius*, ii. 218
 Swim, *air-bag*, i. 57
 Sword-fish, *scomberoidæ*, iii. 622
 Sylviade, *sylvia*, iii. 747
 Symplythum officinale, *comfrey*, ii. 96
 Syngnatha, *chilopoda*, ii. 25
 Syrian dogs'-bane, *asclepiadeæ*, i. 212
 Syringa vulgaris, *ilicæ*, iii. 46

Tatra, gulo, ii. 691
 Takhaitzee, *antelopes*, i. 145
 Tallow-tree, *pentadesma*, iii. 420
 Talpa, *mole*, iii. 243
 Tamatias, *bucco*, i. 637
 Tanagra, *tanager*, iii. 772
 Tanghin, *apocynæ*, i. 174
 Tansey, *compositæ*, ii. 101; *tanacetum*, iii. 772
 Tapirus, *tapir*, iii. 780
 Tarentula, *thrynus*, iii. 437
 Tarea, *tevum*, ii. 444
 Tatouay, *armadillo*, i. 203
 Taxodium distichum, *Schubertia*, iii. 613
 Tea-plant, *thea*, iii. 792
 Teak-tree, *verbenacæ*, iii. 820
 Teal, common, *duck*, ii. 338; summer or gargany, 339; American, summer, 339; blue winged American, 340
 Teazle family, *dipsacæ*, ii. 287
 Tecoma, *bignoniacæ*, i. 379
 Teladu, *marten*, iii. 226
 Telagon, *marten*, iii. 224
 Tellina, *cyclas*, ii. 227
 Tenrees, *centenus*, i. 764
 Termes, *termidæ*, iii. 787
 Tern, *sterna*, iii. 721
 Testudinaria elephantipes, *elephant's foot*, ii. 413
 Tetryn, *scutellera*, iii. 632
 Texas, *yew-tree*, iii. 829
 Thalictrum flavum, *meadow rue*, iii. 228
 Thapsia villosa, *deadly carrot*, ii. 243
 Thar, *antelopes*, i. 138
 Thea, tea, *camelliæ*, i. 682
 Theobroma, *bytterniacæ*, i. 658
 Theophrasta, *clavija*, ii. 62
 Thesium linophyllum, *bastard toad flax*, i. 307
 Three forked hake, *gadoidæ*, ii. 565
 Thistle, *compositæ*, ii. 98
 Thrush, iii. 794; missel, 794; song, 795; ring, 797; solitary, 797; mocking, 798; rust coloured, 801; solitary, 801; Wilson's, 801
 Thuja, *arbor vitæ*, i. 187
 Thyme, *thymus*, iii. 802
 Tiger, *cat*, i. 727.
 Tigridapavonia, *Mexican tiger flower*, iii. 238
 Tillia microphylla, *lime-tree*, iii. 48
 Tillandsia, *bromeliacæ*, i. 631
 Tillidæ, *cleridæ*, ii. 63
 Timamon, *gallinidæ*, ii. 590
 Tipulariæ, *tipulidæ*, iii. 804
 Titan, *cytinæ*, ii. 235
 Tithys, redstart, *black breasted red-start*, i. 505
 Todus, *tody*, iii. 807
 Tomtit, *blue cap*, i. 534
 Tomogerus, *anostoma*, i. 124
 Top-knot, *fat-fish*, ii. 503
 Tope, *shark*, iii. 656
 Torpedo, *raia*, iii. 512
 Torsk, *gadoidæ*, ii. 561
 Tortoise, *chelonia*, ii. 11, 16; sea, 13; fierce, 16; mud, 17; painted, 17; Indian, 18; geometrical, 18
 Tortoise beetles, *cassida*, i. 713

Totanus, *sandpiper*, iii. 604 1
Toton verdadeiro, *armadillo*, i. 202
Trachilus, *humming-bird*, ii. 789
Tragium anisum, *anise*, i. 116
Tragopogon porrifolium, *salsify*, iii. 603
Trapogon, *gallinidia*, ii. 582
Tree-creepers, *certilia*, i. 776
Trefoil, *trifolium*, iii. 811
Trefolium, *clover*, ii. 66
Tribulus, *caltrop*, i. 670
Trichacus, *morse*, iii. 286
Triglochin, *arrow-grass*, i. 204
Trichilium, *ageriedae*, i. 41
Trochilus, *humming-bird*, ii. 787
Trochus, *monodonta*, iii. 284
Trochus perspectivus, *solarium*, iii. 699
Trochus, *pyramidella*, iii. 507
Tropaeolum majus, *Indian cress*, ii. 825
Trout, *salmon*, iii. 596; *salmon*, 594; bull, 595
Trumpeter, *agami*, i. 46
Trumpet flower family, *bignoniaceae*, i. 378
Truncati pennae, *brachinida*, i. 620
Trypeta, *tephritia*, iii. 787
Tsalsalsiya, *ximb*, iii. 830
Tuberous moschatell, *adoxa*, i. 41
Tulip-tree, *liriodendron*, iii. 51
Tunny, *scomberoidae*, iii. 621
Turbo, *cricostomata*, ii. 169; *cyclostoma*, 228
Turbo delphinium, *delphinula*, ii. 271; *monodonta*, iii. 284; *puppa*, 506
Turbo scalaris, *scalaria*, iii. 611
Turbot, *flat-fish*, ii. 502
Turc, *bostrichida*, i. 570
Turdus, *thrush*, iii. 794
Turkey, *gallinida*, ii. 591
Turnip, *crucifera*, ii. 183
Turnip-fly, *hallica*, ii. 699
Turtle, *chelonia*, ii. 11; sea, 13; green, 13; hawk's-bill, or tortoise-shell, 15; logger-head, 15; soft, of the Nile, 16
Turtle dove, pigeon, iii. 462; collared, 463; Carolina, 463; passenger, 464; Cape, 465; Macquarrie, 466
Tusk, *brosmitus*, i. 632; *gadoidae*, ii. 565
Tussilago farfara, *colt's-foot*, ii. 88
Tussilago petasites, *butter bur*, i. 651
Tway blade, *listera*, iii. 51
Two-toed sloth, *unau*, iii. 817
Typha angustifolia, *cat's-tail*, i. 749
Typhograph beetle, *bostrichida*, i. 569
Tyrophaga, *piophilica*, iii. 473

U

ULEIOIOTA, *brontes*, i. 632 .
 Ulex Europæa, *furse*, ii. 556
 Ulmus, *elm tree*, ii. 413
 Upas tree, *apocynæ*, i. 174
 Upupa, *hoopoe*, ii. 767
 Uria, *guillemot*, ii. 677
 Urocerus, *xephydria*, iii. 829
 Ursus, *bear*, i. 321
 Ursus, *boe*, i. 559
 Urutua, *nyctichelidon*, iii. 336
 Utia, *capromys*, i. 93

V

VACCINIUM uliginosum, *bleaberry*, i. 509
 Vagans, *bottle-tit*, i. 611
 Vanellus, *lapwing*, iii. 29
 Venus, *astarte*, i. 227; *cytheria*, ii. 235; *cyprina*, 233; *galathea*, 566
 Venus's fly-trap, *dionæa*, ii. 282; *droseracea*, 330
 Venus's-hair, *adiantum*, i. 36
 Venus navelwort, *omphaloides*, iii. 347
 Verbascum thapsus, *mullein*, iii. 292
 Vermilion, *cinnabar*, ii. 53
 Veronica beccabunga, *brooklime*, i. 632
 Vespa crabro, *hornet*, ii. 769
 Vespertilionidæ, *bats*, i. 312
 Vespidae, *vespa*, iii. 820
 Viburnum, *caprifoliacea*, i. 92
 Viburnum opulus, *guelder rose*, ii. 677
 Viburnum tinus, *laurestine*, iii. 33
 Vinca minor, *periwinkle*, iii. 423
 Viola tricolor, *heart's-ease*, ii. 715
 Viper, *viper*, iii. 821; *anguis*, i. 112
 Viper's grass, *compositæ*, ii. 100; *scorzonera*, iii. 631
 Virginian deer, *deer*, i. 265
 Virginian hemp, *acnida*, i. 26
 Viscacha, *chinchillidæ*, ii. 26
 Viscus album, *mistletoe*, iii. 242
 Vison, *marten*, iii. 219
 Viverra, *citrus*, ii. 57
 Vole, water, *rat*, iii. 538; bank, 541; field, 541
 Voluta, *auricula*, i. 250
 Voluta, *columbella*, ii. 92
 Voluta, *mitra*, iii. 242
 Vulpes, *fox*, ii. 525

W

WALKING-LEAF insects, *phyllium*, iii. 438
 Walnut, *juglandæa*, iii. 2
 Wampee, *cockia*, ii. 136
 Wandaroo, *baboon*, i. 267
 Wapiti, *deer*, ii. 263
 Warbler, *curruca*, ii. 215
 Warblers, *sylvia*, iii. 747; blue-throated, 750; sedge, 759; reed, 760; grass-hopper, 760
 Warty hog, *phascogærus*, iii. 431
 Warty serpent, *acrochordus*, i. 27
 Water calthrops, *trapa*, iii. 811
 Water chestnut, *cyperacea*, ii. 233
 Water-cress, *crucifera*, ii. 183
 Water-hen, *gallinule*, ii. 608
 Water-paranep, *sium*, iii. 694
 Water-pepper family, *elatinea*, ii. 396
 Water star-wort, *callitrichinea*, i. 668
 Waxwing, *bombycilla*, i. 543
 Weasel, *marten*, iii. 217
 Weeping-willow, *salix*, iii. 587
 Whale, common, black, or Greenland, *balæna*, i. 286
 Whales, *cetacea*, i. 778
 Whiff, *flat-fish*, ii. 503
 Whip-poor-Will, *nyctichelidon*, iii. 333
 Whitebait, *herring*, ii. 742
 White tiger, *cat*, i. 732
 Whiting, *gadoidæ*, ii. 562
 Whortle-berry, *ericea*, ii. 441
 Widgeon, *duck*, ii. 340
 Wild apricot, *mammea*, iii. 203
 Wild cat, *cat*, i. 738
 Wild or squinting cucumber, *cucurbitacea*, ii. 202
 Wild spinach, *chenopodea*, ii. 19
 Wind-flower, *anemone*, i. 110
 Woad, *isatis*, ii. 884

Wombat, *phascolomys*, iii. 433
 Woodcock, *snipe*, iii. 696; American, 698
 Woodpecker, *picus*, iii. 440
 Worms, *annelida*, i. 119
 Wormseed, *compositæ*, ii. 101
 Wormwood, *absinthium*, i. 5; *compositæ*, ii. 101
 Wouwou, *ape*, i. 163
 Wrasse family, *labroidæ*, iii. 17
 Wren, golden-crested, *sylvia*, iii. 752; fiery crested, 764; ruby-crested, 755; common, 756; house, 758

X

Xylocopa, *lymesylonida*, iii. 71

Y

Yak, *bos*, i. 562
 Yam family, *dioscorea*, ii. 283
 Yapak, *chironectus*, ii. 28
 Yarrow, *achillea*, i. 24; *compositæ*, ii. 100
 Yellow rattle, *rhinanthus*, iii. 685
 Yew, *conifera*, ii. 131

Z

Zea mays, *Indian corn*, ii. 825
 Zebra, *horse*, ii. 784
 Zeus vomer, *argyreus*, i. 194
 Zibeth, *civet*, ii. 59
 Zingiber officinale, *ginger*, ii. 630
 Zizania aquatica, *Canada rice*, i. 684
 Zyziphus spina Christi, *Christ's thorn*, ii. 34
